Disclaimer

The Global Biodiversity Assessment (GBA) is an independent, peer-reviewed analysis of the biological and social aspects of biodiversity, commissioned by the United Nations Environment Programme (UNEP) and funded principally by the Global Environment Facility (GEF). The contents of the GBA do not necessarily reflect the views or policies of UNEP nor of the GEF, nor are they an official record.

The designations employed and the presentations made do not imply the expression of any opinion whatsoever on the part of UNEP concerning the legal status of any country, territory or city, or its authority, nor concerning the delimitation of its frontiers and boundaries.

Foreword

Biodiversity represents the very foundation of human existence. Yet by our heedless actions we are eroding this biological capital at an alarming rate. Even today, despite the destruction that we have inflicted on the environment and its natural bounty, its resilience is taken for granted. But the more we learn of the workings of the natural world, the clearer it becomes that there is a limit to the disruption that the environment can endure.

Besides the profound ethical and aesthetic implications, it is clear that the loss of biodiversity has serious economic and social costs. The genes, species, ecosystems and human knowledge which are being lost represent a living library of options available for adapting to local and global change. Biodiversity is part of our daily lives and livelihoods and constitutes the resources upon which families, communities, nations and future generations depend.

The basis of any discipline is not the answers it gets, but the questions it asks. As an exercise in biodiversity conservation, a number of questions can be asked: What are the values associated with biodiversity? How can benefits be generated from this resource? How can these benefits be shared in a fair and equitable manner? How do humans influence biodiversity? What are the underlying causes for this influence and what are their ecological consequences? How do the natural dynamics of biodiversity and the human-induced changes in biodiversity affect the values of goods and services provided by biodiversity to society?

Taken together these questions bring out the multi-dimensional challenge that the issue of biodiversity conservation poses to policy-makers and scientists alike.

Fortunately, the international community has recognized this challenge. The entry into force of the Convention on Biological Diversity, in December 1993, is illustrative not only of this recognition but also a change in the overall strategy in conserving biodiversity. It signals a move to a more proactive position that simultaneously seeks to meet people's needs from biological resources while ensuring the long-term sustainability of Earth's biological capital.

The United Nations Environment Programme has played a key role in the development of the issues relating to biodiversity. Our efforts have included the forging of the Convention on Biological Diversity, its follow-up, and have included efforts to strengthen the national and global base of knowledge on biodiversity.

This endeavour lies at the very core of UNEP's three-fold mandate:

- to catalyse awareness on global environmental problems;
- to build consensus on action to address those problems;
- to promote and support successful programmes and activities of a catalytic nature.

An essential element is the collection and dissemination of knowledge generated by scientific research. In this regard the scientific community has been and shall continue to be UNEP's key partner in carrying out our mandate.

It was in this spirit that UNEP commissioned the Global Biodiversity Assessment (GBA) project. Underlying this endeavour was an attempt to mobilize the global scientific community to analyse the present state-of-the-art knowledge and understanding of biodiversity and the nature of our interactions with it: in other words, to provide the scientific information to answer some of the questions posed above.

It must be noted here that, unlike the global agreements on Climate Change and Ozone Depletion, no formal scientific assessment was carried out prior to the final negotiation of the Convention on Biological Diversity. The Parties to the Convention clearly recognize the lack of knowledge regarding biodiversity, and the urgent need to develop our knowledge base in this area. However, let me hasten to add, there have been no formal links between the Assessment and the Convention.

Nevertheless, governments were regularly informed of the progress made in the development of this document. UNEP was gratified when we received written submissions from experts from more than 80 countries, who peer-reviewed various parts of the Assessment in their personal capacity.

The document at hand is the result of an ambitious scientific endeavour, the outcome of the invaluable contributions of more than a thousand experts worldwide. It reflects a broad spectrum of views.

The GBA is an independent critical, peer-reviewed scientific analysis of the current issues, theories and views regarding the main aspects of biodiversity. The Assessment does not concern itself with the assessment of the state of country-level or regional biodiversity. This was the fear expressed by some constituencies when this project was initiated. Its perspective is global with a focus on general concepts and principles. It does

not present any policy recommendations, although it does draw attention to possible policy implications of its major findings and to existing gaps in knowledge and capacity.

Although the GBA does provide an analysis of a wide range of biological and social science issues pertaining to biodiversity, its range is by no means exhaustive. Issues such as fair and equitable sharing of benefits, financial mechanisms and technology transfer have not been treated as extensively as the more scientific issues.

The emergence of new issues – scientific, economic and social – relating to biodiversity in the near future is a distinct possibility. In this context GBA should be regarded as a timely assessment of the subject as perceived by the global scientific community.

UNEP believes that the GBA will provide a compendium of knowledge for the benefit of those

involved in the implementation of the Convention on Biological Diversity and it will also serve as a useful tool for the scientific body of the Convention to begin its work. I also hope that the Assessment will provide a significant conceptual input in the implementation of the relevant chapters of Agenda 21 and some initiatives put forth by the Commission on Sustainable Development (CSD).

Clearly the aim of the Assessment was not to present a consensus document. It is, however, an important step in building scientific consensus and creating the foundation for implementing political consensus. It is my fond hope that this document will succeed on both these counts.

Elizabeth Dowdeswell
Executive Director, UNEP

Preface

Unlike other environmental treaties, such as the Convention on Climate Change and the Montreal Protocol on Substances that Deplete the Ozone Layer, no formal knowledge assessment was carried out prior to the negotiation of the Convention on Biological Diversity. The need for such a comprehensive review of current knowledge in the broad field of biodiversity was recommended to UNEP by the Scientific Advisory Panel (STAP) of the Global Environment Facility (GEF). In response to this challenge, UNEP launched the **Global Biodiversity Assessment** following the submission of a project to the Global Environment Facility for funding. This was endorsed by the Participants' meeting in Abidjan in 1992 for inclusion in the Fourth Tranche.

A Preparatory Group for the Global Biodiversity Assessment (PGGBA) was convened by UNEP's Assistant Executive Director in Montreal, Canada, on 15–16 March 1993. The Preparatory Group discussed the objectives of the proposed Assessment and produced a preliminary outline of its content.

The GBA project was formally approved by UNEP on 3 May 1993 and subsequently it nominated a Steering Group for the Assessment (SGGBA) which met in Trondheim, Norway, on 31 May–2 June 1993. The Steering Group reviewed the policy to be adopted in preparing the Assessment, and after detailed consideration approved a Draft List of Contents. It also developed a timetable and suggested names of potential Section Co-ordinators and Lead Authors.

The method adopted for preparation of the Assessment has clear similarities with those successfully applied by the Intergovernmental Panel on Climate Change and the Montreal Protocol on Substances that Deplete the Ozone Layer. The complexity of the issues led to the establishment of thirteen teams of experts for the preparation of the GBA, each with up to four Co-ordinators and several Lead or Contributing Authors, numbering altogether some 300 experts from over 50 countries. Every effort was made to ensure as broad a geographical balance as possible in the selection of Co-ordinators and authors, and to ensure that both developing and developed countries were adequately represented. A Focal Point Co-ordinator was appointed for each team and the teams were provided with the necessary financial resources to allow them to prepare the text of the Sections. Each team met in one or more

workshops to plan the detailed content of each chapter, exchange views, and allocate responsibilities for particular parts of the text. The workshops were attended by co-ordinators, authors and invited specialists as well as by members of the Management Group. Editorial guidelines were prepared by the Executive Editor who also participated in the development of most Sections. The materials received for each chapter were reviewed and edited by the Focal Point Co-ordinators and then submitted as a first draft of the Section.

During the preparation of the GBA emphasis has been placed on ensuring open-ness, transparency and broad participation. A major feature in this regard has been the submission of the draft text to extensive peer review. Unlike the climate and ozone assessments, the GBA has had no intergovernmental component or direct link to the Convention on Biological Diversity or other intergovernmental process. None the less, governments have been kept informed throughout by means of correspondence, informal contact, and presentations of the GBA in conjunction with intergovernmental meetings. The draft Phase 2 text was submitted to the Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA) of the Convention on Biological Diversity for their use as a background document. Governments were also invited to nominate experts to peer-review the first draft of the GBA in their personal capacity, and nominations were received from about 50 governments. Altogether more than 1100 experts from more than 80 nations have participated in the peer review process and hundreds of written submissions have been made.

Several meetings between the Chairman, Executive Editor, the Co-ordinators and UNEP have been held to review the whole text and detect gaps, overlaps and inconsistencies in the text. They also prepared a first draft of the Summary for Policy-Makers (SPM) and the SPM Editorial Group met on several occasions to finalize the text of the Summary. A second draft of the main GBA was prepared, taking into account the comments received, and this was put through another peer-review process. It was also subjected to a major review in the form of an expert workshop that took place in Panama City from 12 to 16 June 1995. A third draft of the Assessment was then prepared, edited and made ready for publication. A flow chart showing the different

Flow-chart of the various stages of the GBA process.

stages of preparation of the GBA is shown in the accompanying Figure.

In a subject as complex as biodiversity, it is not surprising that many of the topics reviewed in the GBA are subject to different interpretations and viewpoints. We tried to take this diversity of opinion into account. Some topics appear in more than one Section of the GBA when it is necessary to deal with them in different contexts. We have attempted to cross-reference all these cases.

Due to circumstances beyond our control it was not possible to include a Section on the larger dimensions of human values in biodiversity as had been planned. However, arrangements have been made for this to be completed and issued as a separate publication by UNEP.

As Executive Editor, I should like to thank all the Co-ordinators, Lead Authors and their staff for their forbearance and good humour in undertaking all the various phases of preparation of their Sections and in attending to what must have seemed a never-ending set of requests from me for all kinds of information and assistance. I must also pay tribute to the staff of the GBA office in Reading who worked long and hard to see through the final preparation of the manuscripts for the publishers – Anne Phillips, Keith Gardner and Victoria Bonham. My thanks are also due to the staff of Cambridge University Press: Alan Crowden and Maria Murphy, who negotiated the publication arrangements and saw the book through the press, and Tony Tomlinson who, as production manager, arranged for the manuscript to be set, proofed and printed. Jane Bulleid, the copy-editor, performed the heroic task of converting a very large and complex manuscript into a form suitable for printing. Martyn Bramwell undertook a general edit of the manuscripts in record time.

Vernon Heywood
Executive Editor

Acknowledgements

The Global Biodiversity Assessment has benefited from having received contributions from more than 1500 experts from the academic community and international organizations. Many of them have laboured long hours in contributing to the Assessment. Without their dedication, co-operation, advice and support the successful completion of this project would not have been possible. On behalf of UNEP I should like to extend my particular gratitude to the Chair of the Assessment Dr Robert T. Watson, the Executive Editor Professor Vernon H. Heywood and the Section Coordinators for their dedicated work. My sincere appreciation is also extended to the Lead Authors and other Contributors and to the Peer Reviewers for their written contributions and comments. UNEP would also like to thank the Honorary Advisers Dr Peter H. Raven, Professor Emil Salim, Dr M.S. Swaminathan and Professor E.O. Wilson for their support and the members of the Steering Group for the guidance they provided in

the early stages of the GBA. I also wish to acknowledge the valuable work done by the Editorial Group in preparing the Summary for Policy-Makers. UNEP highly appreciates the support from governments and scientific institutions who submitted suggestions for Peer Reviewers. I should also like to extend my thanks to the staff in UNEP and co-operating institutions who contributed in so many ways. And lastly I wish to thank those people who made it possible to meet the ambitious publication schedule of the Assessment – the Publishers Cambridge University Press, the copy-editor, the indexer, designers, graphic artists, production staff, typesetters and printers. To all those who participated in the project UNEP is deeply indebted.

Reuben Olembo
Deputy Executive Director

1.0 Introducing biodiversity

Throughout the world, increasing interest is being expressed in environmental issues, largely as a result of the serious concern that is felt about the present state of both the local and global environment and the predictions that have been made about future trends. This awareness is based on a realization that the state of the Earth's biological systems is of fundamental importance for human society and that our influence on these systems is increasing exponentially. During the last decade, much of this interest and concern has focused on the issue of biodiversity. The scientific and social concepts and issues involved are highly complex and often poorly understood and badly explained. To address these matters, a global science assessment of what is known about biodiversity has been prepared by some of the world's leading natural and social scientists.

Are we facing a global biodiversity crisis, or indeed are we in the midst of one, as several authors have suggested? These and similar questions have been asked during the past two decades, arising out of a growing concern at the prospect of a rapidly accelerating loss of species, populations, domesticated varieties and natural habitats such as tropical rain forests and wetlands. Recent estimates suggest that more than half the habitable surface of the planet has already been significantly altered by human activity (Hannah and Bowles 1995). It has also been suggested that we are on the verge of mass extinctions of species (Myers 1979; Wilson 1985). These concerns have been coupled with a realization that our knowledge of the diversity and variability of plants, animals, micro-organisms and the ecosystems in which they occur is woefully incomplete. It is this situation that led to the introduction of the notion of **biological diversity** – the total variability of life on Earth – which first emerged some fifteen years ago (Lovejoy 1980a, b; Wilson 1985; Norse *et al.* 1986; Wilson and Peters 1988; Reid and Miller 1989; McNeely *et al.* 1990; Chauvet and Olivier 1993).¹

Although the term biological diversity, or its short form **biodiversity**,² is rather new, the origins of the concept go far back in time. Questions regarding the diversity of life have occupied people's minds for as long as we have inhabited this planet. The need to divide the diversity of plants, animals and microorganisms on land and in the oceans, into groups that can be recognized and communicated about, is a basic human trait and allows us to find our way around the planet. Classification is an essential process in our daily lives (Davis and Heywood 1963) and a necessary tool for our survival. For example, we need to know which plants, animals and fungi are useful, and which are poisonous or dangerous. This activity of classifying diversity is known as **taxonomy**. All communities employ what are called **folk classifications** for the species used in everyday life, and these species are

referred to by vernacular names. The first attempts to produce formal classifications of plants and animals go back to the times of Aristotle in the twenty-fourth century BP while modern biological taxonomy dates from the mid-eighteenth century. Our knowledge of the diversity of organisms remained extremely limited until then, but increased greatly during the past 200 years as the world was opened up by exploration, colonization and trade. Nonetheless, even today we are not certain to an order of magnitude how many species occupy our planet, although a working figure of 13 million is accepted here, only about an eighth of which have so far been described. All the species we can observe on the planet today are the result of the processes of evolution through time, and modern taxonomic procedures seek to establish the patterns of evolutionary relationship between them.

Ideas regarding the linkages and relationships between organisms and their environment, both biotic and abiotic (**ecology**), developed from the eighteenth century onwards as naturalists such as Darwin, Humboldt and Wallace observed the patterns of distribution of species and vegetation types in their natural environments, but it was not until the early part of the twentieth century that ecology developed formal tools for the measurement and modelling of these relationships and their diversity. **Ecological diversity** refers to the numbers of species in given areas, the ecological roles that these species play, the way that the composition of species changes as we move across a region, and the groupings of species (ecosystems) that occur in particular areas (such as grassland or forest), together with the processes and interactions that take place within and between these systems. It also covers the diversity of ecosystems in landscapes, of landscapes in biomes and of biomes on the planet.

Again, although some of the basic facts of heredity have been known since biblical times, and deliberate breeding and hybridization experiments have been undertaken since the eighteenth century, formal genetics only started with the experiments of Mendel in the second half of the nineteenth century. The idea of **genetic diversity** is even

1. It appears that the term biological diversity was first defined as including two related concepts, genetic diversity (the amount of genetic variability within species) and ecological diversity (the number of species in a community of organisms) by Norse and McManus (1980); see also Harper and Hawksworth (1994).

2. The contracted form 'biodiversity' was apparently coined by Walter G. Rosen in 1985 for the first planning meeting of the 'National Forum on Biodiversity' held in Washington DC in September 1986, the proceedings of which (Wilson and Peters 1988) brought the notion of biodiversity to the attention of a wide field of scientists and others. Other wide-ranging surveys of the field were published by Reid and Miller (1989), McNeely *et al.* (1990) and Pineda *et al.* (1991).

Figure 1.0-1: The interaction between human society and biodiversity.

more recent and focus on it stems in part from concern at the loss of genetic variability in crop plants, leading to the development of the genetic resources sector which deals with the sampling, collection and storage of the genetic variability of crop varieties and domesticated breeds (Plucknett *et al.* 1987; Juma 1989). Genetic diversity refers to variation within and variation between populations of species, and is measured in terms of, for example, variation between genes or between DNA or amino acid sequences, as well as numbers of breeds, strains and distinct populations. Recent insights into genetic variability and the development of biotechnological techniques have provided us with the means to use and manipulate this genetic information with much greater facility than previously.

Increasing environmental awareness over the past few decades has highlighted the need to enhance our understanding of the ways in which human society and biodiversity interact. The scope of biodiversity has, in consequence, been widened further so as to include the human dimension. We need to understand the cycles of interactions that take place between biodiversity and human society (Figure 1.0-1) and we now have to ask questions

about biodiversity such as: How is it valued in different cultures? How is it influenced by human action and activities? How can biological resources be used sustainably? How can the benefits derived from their use be shared fairly and equitably?

The importance that the global community places on these issues is underscored by the emphasis given to them at the 1992 United Nations Conference on Environment and Development (UNCED) and the entry into force of the Convention on Biological Diversity (CBD) at the end of 1993. About 120 countries are now parties to the Convention, which has become one of the major priorities amongst environmental issues. As a consequence, conservation of biodiversity, the sustainable use of its components and the fair and equitable sharing of its benefits have acquired a new political dimension, both globally and nationally. They are now firmly on the agenda of each signatory state and this has led to the need for a close analysis of all the issues raised by the provisions of the Convention and a search for ways in which they can be implemented effectively.

1.1 Aims and objectives

1.1.1 Objective of the Assessment

The objective of the Assessment is to:

provide an independent, critical, peer-reviewed, scientific analysis of the current issues, theories and views regarding the main global aspects of biodiversity. It assesses the current state of knowledge, identifies gaps in knowledge and critical scientific issues, and draws attention to those issues where scientists have reached a consensus of view and those where uncertainty has led to conflicting viewpoints and therefore a need for further research.

About 1500 scientific experts from all over the world have contributed to its preparation and pooled their knowledge, so as to present here as comprehensive and balanced a picture as possible of the many and varied components that go to make up biodiversity. It is believed that this assessment will constitute an important basis for decision-making and for further research in the field of biodiversity at all levels of society, locally as well as globally. The perspective in the GBA is global, like the international science on which it is based, with a focus on general concepts and principles. It is hoped that this perspective will assist both the global community and individual countries when addressing their particular biodiversity challenges.

1.1.2 Linkages with the Convention on Biological Diversity and other initiatives

The Convention on Biological Diversity (CBD) was negotiated prior to the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in 1992. It entered into force on 29 December 1993 and is one of the most significant and far-reaching environmental treaties ever developed (see Box 1.1-1).

The Convention states in its preamble that The Contracting Parties are 'aware of the general lack of information and knowledge regarding biological diversity and of the urgent need to develop scientific, technical and institutional capacities to provide the basic understanding upon which to plan and implement appropriate measures'.

This recognition is also the basis for the GBA but apart from this recognition there have been no formal links between the Assessment and the Convention. The Assessment has not been part of the Convention process and indeed UNEP and the Management Group have been at pains to avoid any sense of attempting to pre-empt the Convention, its mechanisms or its actions. The GBA is not an official statement on global biodiversity as such: rather it is a considered view by the world's scientific community on the state-of-the art in our knowledge and understanding of the multitude of issues involved in biological diversity.

Box 1.1-1: The Convention on Biological Diversity.

Preparations for a Convention on Biological Diversity were initiated by the Governing Council of UNEP in 1987 through the establishment of an Ad Hoc Working Group of Experts on Biological Diversity which met in 1988. The Ad Hoc Working Group was followed in 1991 by an Intergovernmental Negotiating Committee for a Convention on Biological Diversity. The agreed text of the Convention on Biological Diversity (CBD) was adopted by 101 governments in Nairobi in May 1992 and signed by 159 governments and the European Union at the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in June 1992. The Convention entered into force on 29 December 1993 and the first meeting of the Conference of Parties was held in Nassau, Bahamas, in November–December 1994. About 120 governments are now parties to the Convention.

The broad scope of the convention is illustrated in its Article 1, Objectives, which states:

The objectives of this Convention, to be pursued in accordance with its relevant provisions, are the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding.

It is not the objective of the GBA to develop recommendations, although occasionally it draws attention to possible policy implications of its major findings, and to gaps in knowledge or capacity. The Assessment is a compendium of knowledge which can be drawn upon by decision-makers, officials, scientists and any others who are involved in the follow-up and implementation of the Convention on Biological Diversity. It is expected that the Assessment will be useful for the implementation of several Chapters of UNCED Agenda 21, such as Chapter 15 on Biodiversity and Chapter 16 on Biotechnology, as well as for the FAO Undertaking on Plant Genetic Resources.

It is also believed that the GBA will provide a significant conceptual input in several initiatives put in hand by the Committee on Sustainable Development (CSD), for example with regards to issues of forestry and oceans.

An analysis of our knowledge of measures that can promote fair and equitable sharing of benefits from the use of genetic resources is not specifically addressed in the Assessment. Nor does the Assessment address measures for

Box 1.1-2: Some recent international biodiversity initiatives.

The **UNEP Biodiversity Country Studies Project**, initiated 1991, consisting of bilaterally and GEF-funded studies in developing countries, implemented in co-operation with donor countries and UNDP. Nineteen studies have been completed and several more are in preparation;

- **Global Biodiversity Strategy.** Guidelines for Action to Save, Study, and Use Earth's Biotic Wealth Sustainably and Equitably. WRI/ IUCN/UNEP, Washington DC (1992);
- **Global Biodiversity: Status of the Earth's Living Resources.** World Conservation Monitoring Centre. Chapman & Hall, London (1992);
- **Caring for the Earth: A Strategy for Sustainable Living.** IUCN/ UNEP/ WWF, Gland, Switzerland (1991);
- **Global Marine Biological Diversity: A Strategy for Building Conservation into Decision Making.** Center for Marine Conservation. IUCN/ WWF/ UNEP, The World Bank. E.A. Norse (ed.). Island Press, Washington DC (1993);
- The Proceedings of the **Norway/UNEP Expert Conference on Biodiversity.** O.T. Sandlund and P.J. Schei (eds). Directorate for Nature Management/Norwegian Institute for Nature Research, Trondheim (1993);
- **From Genes to Ecosystems: A Research Agenda for Biodiversity.** O.T. Solbrig (ed.). IUBS/SCOPE/ UNESCO, Paris (1991).

technology transfer or financial mechanisms. These are important issues in the Convention on Biological Diversity. They were not included in the GBA at the time of its initiation because they were seen as being somewhat outside the scope of such an apolitical scientific assessment. Occasional reference will be made to these issues but a separate Assessment would be needed if they were to be explored fully. They are, moreover, matters that the Conference of the Parties to the Convention (CBD) may wish to address through the activities of the Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA) or some other mechanism.

The GBA represents the first comprehensive, global, scientific knowledge assessment to be carried out in the broad field of biodiversity. Its preparation has been based principally on an assessment of the relevant scientific literature, taking into account other major biodiversity initiatives, both national and international. It is, however, quite independent of any of these. Some of the more important initiatives in the field of biodiversity that have taken place outside the CBD process are given in Boxes 1.1-2 and 1.1-3.

1.2 Defining and characterizing biodiversity

The multifaceted nature of biodiversity is reflected in the many definitions that have been put forward. Perhaps the first definitions to recognize specifically the three principal components (ecosystems, species and genes) in common use today (e.g. Chauvet and Olivier 1993; Barbault 1994),

were published by Norse *et al.* (1986), and the United States Office of Technology Assessment (OTA 1987). These three major components of biodiversity are recognized in the definition adopted in Article 2, Use of Terms, in the Convention on Biological Diversity, as follows:

'Biological diversity' means the variability among living organisms from all sources, including, inter alia, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems.

Strictly speaking the word biodiversity refers to the quality, range or extent of differences between the biological entities in a given set. In total it would thus be the diversity of all life and is a characteristic or property of nature, not an entity or a resource. But the word has also come to be used in a looser fashion for the set of diverse organisms themselves, i.e. not the *diversity* of all life on earth, but *all life itself*. In some contexts the usages are distinct, in others there is ambiguity. 'A biodiverse ecosystem', or 'the generation of biodiversity in rain forests' clearly refer to the quality or range of diversity. 'Who owns the biodiversity of the forest?', 'Let us list the biodiversity present in this one ecosystem' are in contrast references to the forms that exist, albeit in a diverse system, rather than the actual diversity among them.

In addition to this duality of usage, biodiversity is, not surprisingly, perceived differently by different interest

groups. Thus the scientist studying the maintenance of biodiversity in ecosystems may focus on processes which maintain the variety of organisms, regardless of which ones they are. By contrast, a lawyer establishing legal rights over the biodiversity of a national park may be thinking purely of the set of objects, the plants, animals or microbes, and very definitely which ones they are, rather than the variation between them. Similarly, perceptions will differ between those who live in developed and developing countries and between those who live in cities and rural areas.

While the imprecision of definition and diversity of perception are sometimes viewed as a weakness of the concept of biodiversity, they can also be considered a strength in making biodiversity a unifying concept, bringing together people from different disciplines and interests with a common goal – the understanding, conservation and wise use of biological diversity and resources (Heywood 1993).

For the purposes of the the Global Biodiversity Assessment, biodiversity is defined as the total diversity and variability of living things and of the systems of which they are a part. This covers the total range of variation in and variability among systems and organisms, at the bioregional, landscape, ecosystem and habitat levels, at the various organismal levels down to species, populations and individuals, and at the level of the population and genes (see Box 1.2-1). It also covers the complex sets of structural and functional relationships within and between these different levels of organization, including human action, and their origins and evolution in space and time.

Looking more closely at the three components by which biodiversity is most conveniently assessed (Box 1.2-1), they all have a hierarchical nature and overlap. Each is

covered by a major biological discipline (Box 1.2-2) – ecology, genetics and taxonomy – although the taxonomic hierarchy (which provides the framework for organismal diversity) does not strictly speaking include populations and individuals as named units. The population can be seen as the linking unit: it has in fact merited its own field, population biology. Section 2 of the Assessment discusses the way in which biodiversity in these various component fields and levels is characterized, and establishes a vocabulary for subsequent sections.

The **species** is the basic unit of classification and the most practical and commonly used currency when referring to biodiversity (Section 2.1). When biologists talk of organisms they nearly always refer to species, rather than individuals or populations. Although the species may be defined as a group of similar organisms that interbreed or share a common lineage of descent, there is no universal agreement on how to define a species: in practice, concepts differ from group to group. Issues that have to be addressed include: What effects has such uncertainty had on our understanding and handling of biodiversity? How far are we handicapped by the lack of comparability between species in different taxonomic groups, such as flowering plants and bacteria? Is a unifying concept likely to be achieved, and how desirable an objective is this?

While species are for many purposes the basic unit of biodiversity, they are made up of populations (rarely a single one). The local breeding population is the fundamental unit on which evolution and natural selection operates. Populations may vary in size from handfuls of individuals (even a single individual in extreme cases) to hundreds of millions. These individuals contain genetic information and it is this genetic diversity (Section 2.2)

which determines their survival and evolutionary fate and which therefore underlies species diversity. It is the selection and manipulation of genetic variability in crop plants and domesticated animals that provides the raw material of agriculture.

Species do not occur in isolation but exist in a very wide array of ecological groupings, which we can recognize as distinct. These, together with the physical environment, form the main ecoregions and biomes of the world – the habitats for humankind. As discussed in Section 2.3, a universal classification of Large Marine Ecosystems has been developed for the oceans but there is no equivalent for terrestrial ecosystems. Also addressed are the questions of how effective are the various methods used for comparing terrestrial ecosystems or units of vegetation, and the restraints on preparing a unified system.

Separating biodiversity into three components – genetic, organismal and ecological – is not without its difficulties since they are intimately interlinked and actions at any one level will impact on other levels of the hierarchies. Each of the three corresponding disciplines – genetics, systematics and ecology – has tended to view biodiversity as referring primarily to its own component and only very recently have we seen attempts to unite the components in a universal paradigm (Cousins 1994; Huston 1994; Jones and Lawton 1994).

1.3 The coverage of the Assessment

The GBA can be considered under three main themes: the biological issues of biodiversity (Sections 2, 3, 4, 5 and 6); the ways in which biodiversity interacts with humans and how it is valued by them (Sections 11 and 12); and the strategies, techniques and resources by which it may be conserved and used sustainably (Sections 7, 8, 9, 10 and 13).

1.3.1 Biological aspects

1.3.1.1 The magnitude and distribution of organismal diversity

The coverage of the Assessment is intended to be comprehensive in terms of the classes of organisms discussed and the range of ecosystems considered. Thus it deals with both wild and domesticated plants and animals, and with fungi, protoctists, bacteria and viruses. It treats terrestrial, soil, aquatic and marine ecosystems, including natural, semi-natural and human-dominated habitats.

As discussed in Section 3.1, our knowledge of the living world is remarkably limited as regards the number of species we have described scientifically. It is only for certain groups such as birds, mammals and flowering plants that our level of knowledge is reasonably comprehensive. The species we know and have described tend to be those that impinge on human life or activities – be they social, aesthetic or economic. As regards the rest, we have so far learned to live remarkably successfully with ignorance, although calls have been made in recent years to ‘complete the inventory’ of the Earth’s species, through initiatives such as *Systematics Agenda 2000* (1994). How much effort needs to be placed on the cataloguing and description of species and the elucidation of their relationships? Can we, and indeed should we, aim to describe all the species of organisms living on our planet? What priority should be given to this goal relative to other aspects of biodiversity conservation and understanding? On which groups of organisms and in which ecosystems should such efforts be focused?

As pointed out in Section 2.1, what information we do have about species is often poorly organized. For example, there is no global master list of the species that are recognized today. Also, the specimens and associated descriptions of species are widely dispersed, frequently outside their countries of origin and difficult to locate. The extent to which this hampers accurate communication about biodiversity and the options for and ways of resolving the problem are also discussed in Sections in 2, 7 and 8.

Species richness alone is not an adequate measure of the biodiversity of organisms. As shown in Section 2.1, it may also be necessary to consider ‘higher’ groups such as phyla and kingdoms, as well as their evolutionary or phylogenetic positions, when making comparisons of the biodiversity of particular areas. For example, the ‘value’ of an individual species will depend in some circumstances on its evolutionary distinctiveness. Recently, various measures of ‘taxic diversity’ have been proposed to deal with this. Section 2.1 discusses the extent to which these contribute to biodiversity measurement while questions about what their role should be in determining conservation priorities are considered in Section 13.

Species and their populations vary widely in their abundance and geographical distribution. As considered in Sections 3.3 and 3.4, some are cosmopolitan, some are

continental in scale, some show disjunct distributions between continents, and yet others are restricted (endemic) to single countries, islands, mountain tops or even individual rocks. Natural distribution patterns have been severely altered over the centuries by human activities, particularly as a consequence of increased global communications and travel (see Sections 6 and 11).

1.3.1.2 *The dynamics of biodiversity: genetics, speciation and extinction*

Biodiversity is dynamic: species and their populations are in a constant state of evolutionary change. They vary in distribution from year to year and the ecosystems in which they occur are in a constant state of flux. All these changes, as well as human-induced modifications of biodiversity, must be seen against the background of its 3.5 billion year history.

The patterns of present-day diversity of organisms result from the combined effects of speciation (diversification) and extinction. To understand these, we have to investigate the underlying (genetic) processes involved, estimate the relative past and present rates at which they occur and try to distinguish how these rates are being altered by human activities (Sections 4 and 11).

Until recently our knowledge of biodiversity at the genetic level has been limited mainly by the availability of techniques for its study, a situation that has now been reversed as new and sophisticated techniques are increasingly becoming available and being applied to more and more species. It is evident from these studies that for most species a vast amount of genetic diversity exists in

their populations and individuals (see Section 3.1). But what is the actual relationship between genetic diversity and the continued survival and adaptation of species? How is this diversity partitioned – is it mostly within or between populations? Do we need to maintain *all* the diversity within a species or are some components of it more important than others for survival and adaptation? What processes or driving forces may lead to loss or erosion of this diversity in wild populations, and to what extent do reductions in diversity occur as species are fragmented or reduced in geographic range? (See Section 4.2.)

The processes by which species evolve are discussed in Section 4.3. This raises the issue of the ways in which human activities might be affecting the rate of ‘natural’ speciation (as opposed to domestication). For example, while geographical isolation is considered a driving force bringing about speciation, what are the effects of fragmenting previously continuous habitats, and of creating ‘new’ ones such as urban areas? Is the overall global homogenization of habitats reducing the potential for speciation? One way by which humans have clearly accelerated the diversification process is through artificial selection and breeding of domesticated plants and animals (Sections 2.2 and 11). This diversification is likely to accelerate with increasingly efficient methods of manipulating genetic material through biotechnology, which is considered by Section 10.

When we come to consider the rates at which species have become extinct in the past, in response to major climatic, geological and other events, the principal sources of data are: the geological and fossil records (Section 4.1),

Box 1.2-2: The biological disciplines of biodiversity.

- **Evolutionary biology** provides the intellectual and conceptual background for all modern biological science. It provides explanations of how biodiversity arose, and the processes, such as speciation and extinction, by which it continues to change.
- **Taxonomy** is the practice by which the different groups of organism are described and classified in a hierarchical system and thereby provides a reference system for biology. Scientific classifications are the means we use for dividing up the world of organisms into usable units about which we can communicate. **Biological systematics** is the approach whereby similarities and differences between these groups are examined and their evolutionary relationships elucidated.
- **Ecology** deals with the relationships, both structural and functional, between organisms and the biotic and abiotic environments in which they occur, and provides a classification of the different types of habitat.
- **Genetics** seeks to understand the hereditary basis of variation and evolutionary change at all levels.
- **Population biology** brings together information about the genetic structure, spatial, age and size structure, and dynamics of populations of plants, animals and micro-organisms. The population is the fundamental linking unit between the three biodiversity components.

written historical records (Section 11.1), and information derived from living organisms in the form of inherited characters, access to which has been greatly increased by the wider availability of genetic techniques (Section 4.1). Although biodiversity as a whole has clearly increased with time, we need to ask questions such as: Has this been a roughly linear process or have there been wide fluctuations, such as periods of rapid speciation or mass extinction?

A great deal of attention has been focused recently on the possibility that we are facing a mass extinction spasm, the like of which has not been seen before in the fossil record. In fact, the rate at which species are likely to become extinct in the near future is very uncertain. If we look at the number of recorded species extinctions since 1600 it is barely in four figures, which contrasts with several predictions of imminent or actual massive extinctions that have been made in the period 1980–95, based mainly on a species–area model derived from the field of island biogeography. This discrepancy between field knowledge and predictions; the applicability of the model to continental situations, where ecosystem fragmentation as much as loss of area is the important consideration; and other ways of predicting rates of extinction, are reviewed in Section 4.4. Also, from what we know and can predict of present extinction rates, how do they compare with the historical record? Can we meaningfully talk about ‘background’ rates of extinction as a means of comparison? How and where are the known and likely extinctions happening? Since species–area calculations produce predictions for the number of species that are committed to extinction, how long will they be able to persevere before actually going extinct? Will the time-lag be long enough for us to ‘rescue’ or restore many of them? Since most of our information on extinctions derives from a few groups of organisms, notably flowering plants, mammals and birds, how far can we extrapolate to other groups such as nematodes and insects?

Whatever the uncertainties may be about the scale of extinctions, what is clear is that many species will be reduced to small and fragmented populations in the near future. Conserving these will require intimate knowledge of the biology of small populations. This raises the issue of ‘minimum viable population’ (MVP) levels, below which species maintain insufficient numbers to prevent them from being ‘committed to extinction’. The efforts now being made to calculate these levels are discussed in Section 4.2.

1.3.1.3 The dynamics of biodiversity: ecosystem functioning

Ecological communities, together with the physical environment, form the main ecoregions and biomes of the world. Each kind of ecological community provides a range of services on which we depend, such as watershed protection, soil stabilization and pollution control, as well as providing the environmental context in which species

exist. Section 5.1 provides an overview of these services. Those provided by individual biomes, and the way in which they relate to biodiversity, are elucidated in Section 6.

The continued functioning of ecosystems is dependent on their constituent species and their distribution, as well as on the genetic variation within those species (see Section 5.2) and the dynamics of the interactions that exist between different species and between them and the physical environment. Disturbance is a key factor in analysing the dynamics of communities and its role on the functioning and maintenance of ecosystems is assessed in Section 5.3. Questions raised there include: How are humans changing disturbance regimes? Are these changes always negative, at local or global levels?

The extent to which humans are modifying or converting ecosystems in the various biomes is reviewed in Section 6. What is the rate of desertification of the drier areas of the world? How accurate are our estimates of recent and current rates of conversion of tropical forests, both humid and dry? The problems and challenges of monitoring such changes are discussed in Section 4.

A question frequently raised is that of whether all the diversity of species is needed. This raises the question of just how much functional redundancy there is in ecosystems. Are all the species in them necessary for the maintenance and survival of the ecosystem? Or are there keystone species or clusters of species? What levels of species diversity are needed to maintain the functional efficiency and richness of our landscapes? Or are other factors more important? These and related topics are discussed in Sections 4.5 and 5.2, as well as throughout Section 6. Even where species appear to be sufficiently similar to others (with respect to their functional roles) for their loss not to have any immediate consequences, do we know what will happen over long periods of time?

Since many organisms, such as migratory birds and fish, are dependent on more than one ecosystem during their life cycles, it is essential to consider ecosystem functioning at different spatial and temporal scales, a theme which underlies Sections 6 and 7.

1.3.2 Human society and biodiversity

Although biodiversity can be considered a synthesis of the various biological disciplines that contribute to it (see Box 1.2-2), it clearly covers issues far beyond the confines of biology. We also need to understand the evolution of human society and its relationship with biological diversity (Section 11.1). Thus it is also necessary to include insights from the socioeconomic and applied sciences.

1.3.2.1 Cultural diversity

The values, driving forces and human influences, as well as the measures for the conservation and sustainable use of biodiversity, vary greatly within and between different cultures. This aspect of biodiversity is, therefore,

sometimes referred to as **cultural diversity**, recognizing the important role of sociological, ethical, religious and ethnobiological values in human activities. The different cultural dimensions in different parts of the world have played a major role in the ways in which biodiversity is perceived, maintained, preserved, used and appreciated. In the past, high levels of cultural diversity have been dependent on high levels of biological diversity which in turn supported them. The importance of this interdependence is now beginning to be recognized again in traditional resource management systems in many developing countries (Gómez Pompa and Jiménez-Osornio 1989; Gadgil and Berkes 1991).

An understanding of the many aspects of human influences on biodiversity, and their underlying driving forces, is of crucial importance for setting priorities and directing conservation and sustainable use measures. How can the different human influences and social and economic driving forces be categorized, and how are they linked (Section 11.2)?

As scientists we now generally consider that humans form part of global biodiversity although until recently the human species was treated by science as separate from the rest of nature. We now recognize the extent of the effects that humans had on biodiversity in the past; Section 11.1 reviews the history of these effects and compares how different cultures have used and valued biodiversity and the resources obtained from it. The section also addresses basic issues such as: What lessons can we draw from history and different cultural experiences?

Only recently have the overall scale and global implications of human activities on biological diversity been widely appreciated, largely because the changes they cause are the result of an accumulation of countless small-scale actions (Orians 1993). Another reason for the change in our perception was the change in magnitude of this transformation of the biosphere. As cogently summarized by Kates *et al.* (1990):

The magnitude of human-induced environmental change at the global scale is enormous. Transformed, managed and utilized ecosystems constitute about half of the ice-free earth; human-mobilized material and energy flows rival those of nature. The greater part of change in most of these components of the biosphere over the last three centuries has been human-induced.

Globally, humans are now the dominant influence on biodiversity. For example, one recent study has estimated that today humans use or pre-empt *c.* 40% of the terrestrial component of net primary productivity (total photosynthetic production) (Vitousek *et al.* 1986), although this is difficult for us to conceive or perceive. The main forces driving the global transformation of the biosphere –

human population growth, together with increasing resource consumption and socio-cultural change – are continuing to increase, so that this figure is still likely to rise considerably. This raises the question of the carrying capacity of the planet and whether we can continue to increase our demands on it without limits (Section 11).

It is clear that no part of the world can be considered truly ‘undisturbed’: the world’s habitats have been so significantly modified by human action that terms such as ‘undisturbed’ or ‘virgin forest’ are nowadays considered of little value (Section 11.2). The different ways in which human influences affect biodiversity, at all its different levels, are considered under five main headings in the GBA (Section 11.2): (1) agriculture and fisheries and the overharvesting of resources; (2) habitat destruction, conversion, fragmentation and degradation; (3) introduction of exotic or invasive organisms and diseases; (4) pollution of soil, water and atmosphere; and (5) global change. Sections 4, 5 and 6 address the biological effects of these influences, raising questions about their effects on the maintenance and survival of species and populations, the health and productivity of ecosystems, and the biological and ecological integrity of human-modified ecosystems. Can we perceive or predict the long-term effects of these actions, particularly ecological ‘knock-on’ effects such as occur when top predators or pollinators are eliminated from an ecosystem? How do these changes eventually impact on human society?

Many of the changes observed in our landscapes are due almost entirely to the effects over the centuries of agriculture, silviculture, road building, industrial development, urbanization and pollution. These changes have often led to a series of fragmented landscapes consisting of mosaics of human-dominated vegetation interspersed with small patches of ‘natural’ or ‘semi-natural’ vegetation. This Assessment deals, therefore, not only with ‘natural’ or ‘semi-natural’ ecosystems but also with those that are human-dominated such as crop lands, grazing lands, plantation forests, industrial crop plantations, wastelands and areas that are set aside from agriculture. Indeed most biodiversity exists in human-dominated ecosystems (Pimentel *et al.* 1992). Section 13 discusses these issues and such points as: Do the newer concepts of landscape ecology, ‘cultural landscapes’ and the bio-regional approach to conservation and sustainable use and management of resources require the setting of new targets and goals? How do they provide more effective approaches to familiar challenges?

How much attention should be paid to the new patterns of biodiversity that have been created by humans through planting trees, shrubs and other ornamentals in parks and gardens, in street and roadside plantings, and in rehabilitated habitats in industrial and urban situations? A large part of the human population now lives in or around

cities and by the year 2025 an estimated 80% of the residents of developed countries will live in cities while throughout the world only 40% will live in rural areas (UN 1989). Urban and peri-urban biodiversity is therefore of major importance for scientific, cultural and educational reasons. How far should it be encouraged? What role does it play? Some would argue that such 'artificial' (i.e. human-generated) biodiversity should not be our concern (Angermeier 1994) and that we should not advocate the protection of diversity but rather the protection of ecological integrity (Angermeier and Karr 1994). But as already noted, so much of biodiversity has been modified by human activities, and in so many ways, that it is now virtually impossible to draw a clear dividing line between what is 'natural' and what is 'artificial'.

It is often pointed out that most of human nutrition is obtained from a handful of crop plants such as maize, wheat, rice, potatoes, cassava, plantains, peas, beans and lentils, supplemented by a small number of domesticated animals. Given the enormous diversity of species that are believed to exist, this raises the question of the extent to which we need all these species. As pointed out in Section 11, this apparent dependence on a small number of species, especially of the plant world, is misleading: in fact tens of thousands of plant species and a considerable number of animals species are used in local traditional economies. Plants used in traditional medicine alone amount to some 25 000–30 000 species.

Traditional methods of plant and animal breeding have played a major role in shaping significant parts of the Earth's biodiversity during the last few millennia (see Sections 2.2, 11). In its modern guise, biotechnology and gene transfer methods involving plants, animals and micro-organisms are powerful tools with huge potential impacts (Section 10). These techniques can give added value to elements of biodiversity and thus may contribute to a change in conservation priorities (Reid *et al.* 1993). Focus on the use of genetic resources, and the fair and equitable sharing of the benefits arising out of their use, are central issues in the Convention on Biological Diversity. Questions arising out of this (Sections 10, 13) include: What are the risks of relying on such a narrow range of genetic resources? What are the impacts of biotechnology on genetic resources and on biodiversity in general? How can any negative impact be reduced or avoided?

1.3.2.2 *The values of biodiversity*

Today there is world-wide concern at the extent to which biodiversity is being lost and at the same time a growing appreciation of the importance of this diversity, whether measured in economic, social, aesthetic or moral terms. Indeed, it has been pointed out by philosophers of science that, although scientists often insist that their work is value neutral, conservation biologists need to acknowledge that

ethical conflicts frequently underlie the problems they study (Noss 1992). Parallel to the hierarchies of biological organization (Box 1.2-1) they recognize another hierarchy, which has been called an ethical sequence by Leopold (1949). This sequence runs from concern for self, through that for family, social group and species and beyond, through individuals of other sentient animals, and all other species, to a broad 'ecosystem–land–Earth' concern, equivalent to a 'broader ecological self' (Noss 1992). An explanation for the apparent obsession of humans with the diversity of the natural world has been proposed by E.O. Wilson (Wilson 1984; Kellert and Wilson 1993) as the 'biophilia' hypothesis – that human evolutionary history has led us to have an innate tendency to focus on life and life-like processes and that affiliating with other forms of life is a basic human need, materially, intellectually and spiritually. On the other hand it may be argued that civilization has led to our turning away from nature as a source of values in favour of other value systems, especially consumption of biological resources. Our concern with diversity has also been interpreted as part of the innate human need to dominate our environment by classifying and ordering the objects and organisms it houses.

The values placed on biodiversity are strongly linked to the human influences on it and their underlying social and economic driving forces. They are also dependent on some degree of knowledge of the scientific role of particular elements or processes of biodiversity in the functioning of our ecosystems and societies. It is a widely held view amongst environmentalists that environmental values transcend economic costs (Turner and Pearce 1993). However, while it is undoubtedly true that the multiple values of biodiversity are not adequately captured in its market value, if we want to commit and prioritize resources to its conservation and sustainable use, then applying economic measures to its evaluation is unavoidable. Section 12 introduces the field of environmental economics and explores the complex relationship between ethical, environmental and economic values. Questions raised include: How important is biodiversity for humanity? How can known and potential values of biodiversity be categorized, assessed and measured? Can distinctions be usefully made between local and global values of biodiversity? How well are biodiversity values presently reflected by market values? What can be done to reflect more adequately biodiversity values in economic analyses?

A key part of the development of environmental economics is the provision of incentives. How can the benefits derived from individual biological resources be balanced against the social costs caused by the loss of the diversity of organisms? If individuals are to have the incentive to forgo direct economic benefits in order to conserve biodiversity for greater social or global benefits, then what mechanisms must be established to return a share

Box 1.3-1: Conservation, preservation and sustainable use.

The notion of biodiversity is closely associated with that of its conservation, preservation and sustainable use, especially following the publication of the *World Conservation Strategy* (IUCN 1980), the report of the World Commission on Environment and Development (*Our Common Future*) (WCED 1987), *Caring for the Earth: A Strategy for Sustainable Living* (IUCN/UNEP/WWF 1991), and the *Global Biodiversity Strategy* (WRI/IUCN/UNEP 1992). The notion of sustainability is regarded as a guiding principle for development (hence ‘sustainable development’) and development is sustainable only if it is ecologically sound. The tortuous relationships between conservation and sustainability and the many different ways in which the latter concept has been defined are the subject of intense and continuing debate. These are discussed in Sections 12 and 13.

Conservation is a term not defined in the Convention on Biological Diversity. The term is used here both in the narrower sense of **preservation** or maintenance of some or all of the components of biological diversity, and in the broader sense to include also sustainable use of the components, or their recovery or restoration – or both. There are occasions when it is useful to refer to these different components separately although in practice the concepts are intimately linked.

Sustainable use is employed in this Assessment according to the definition given in the Convention on Biological Diversity:

‘*Sustainable use*’ means the use of components of biological diversity in a way and at a rate that does not lead to the long-term decline of biological diversity, thereby maintaining its potential to meet the needs and aspirations of present and future generations.

It does not, however, carry with it the implication that the biodiversity or resources can be handed on to future generations completely unchanged. Virtually all forms of use lead to some change or loss in biodiversity, however small.

of these global and social benefits to those individuals? Which land tenure and property regimes give the greatest incentives for conservation and sustainable use of biodiversity? Such questions are addressed in Sections 11 and 12.

1.3.3 Strategies for biodiversity conservation and sustainable use

1.3.3.1 Basic principles

As emphasized by the Convention on Biological Diversity, any strategy to slow the loss of biodiversity and to enhance its contributions to development must integrate three essential elements: conservation of biodiversity, sustainable use of its components and the equitable sharing of benefits (Box 1.3-1). In the development of national strategies and action plans, as called for in the Convention on Biological Diversity, we need to know if there are conceptual approaches available to address conservation and sustainable use in broad terms: internationally, nationally, or locally, in a bio-region, landscape or ecological community, for instance. We need to ask questions such as: How can we alter social and economic driving forces? What kind of legislative measures are needed for conservation and sustainable use? How can we effectively use and co-ordinate the current data on biodiversity, and deploy the available human resources and the wide array of available conservation techniques? And how can we

integrate conservation and development programmes? Chapter 1 of Section 13 of the GBA aims to provide an over-arching conceptual framework for handling the enormous challenges involved in developing an integrated approach to conservation.

The issues of scientific uncertainty and scientific debate are recurrent themes in the Assessment and are addressed in each section. Managing with these uncertainties is one of the greatest challenges faced by scientists and decision-makers in the field of environment and development, for example with regard to social and economic factors, value estimates, ecological fluctuations, immediate and long-term effects of human impacts and effectiveness of measures. The Convention on Biological Diversity does specifically address the issue of scientific uncertainty with regard to biodiversity in one section of its preamble:

Noting that where there is a threat of significant reduction or loss of biological diversity, lack of full scientific certainty should not be used as a reason for postponing measures to avoid or minimize such a threat.

This concern is related to what is often referred to as the **precautionary principle**, which states that policy-makers should proceed cautiously when making interventions in the natural environment so as to safeguard against unexpectedly

severe future costs. It has to be used prudently, however, and should be applied only when there is a serious probability of adverse consequences. It must not be used as a blanket prescription for inaction in the face of uncertainty.

1.3.3.2 Conservation approaches

Traditionally, conservation has been polarized into two separate approaches: *ex situ* and *in situ*, with ecologists and many conservationists expressing strong preference for the latter while agriculturalists and species-orientated biologists have emphasized the former.

It is almost a truism that the conservation of biodiversity is best achieved in the wild, i.e. in 'natural' ecosystems. This is, however, an oversimplification. In the case of domesticated diversity, considerable effort has been invested in recent decades into conserving *ex situ* the genetic variability represented by the hundreds of thousands of land races or primitive cultivars that have arisen in the relatively small number of crop species that humans have cultivated on a large scale over the last several thousand years, as well as the much smaller number of races of animals they have domesticated. This variability, referred to as **genetic resources**, is maintained in various forms of gene bank for future use in breeding programmes, as discussed in Sections 2 and 8. How much further effort is needed to sample and store the genetic variability in these crops and domesticated animals? How effective and efficient are the different methods of storage? How extensive and how serious is the loss of genetic diversity (genetic erosion) in crop cultivars? Should more effort be invested in developing genetic resources of minor crops and species used in local indigenous economies, including, for example, medicinal plants? Not only are *ex situ* culture collections vital for the maintenance of micro-organisms, but they are also the only effective way by which we can have access to them or indeed determine their very existence.

Current approaches to conservation are in fact very different from those in use until recently. In the last few years, there has been a paradigm shift by conservationists from viewing conservation as essentially a matter of protecting areas and ecosystems (*in situ* conservation) to a much more open and integrated approach. The earlier view was characterized by setting aside and fencing off areas or samples of ecosystems (protected areas), using a minimum of intervention and management. The objective was to maintain the maximum amount of diversity (ecosystem or species), and allow the fenced-off species to continue evolving – the so-called 'hands-off' approach. In special circumstances, the protected areas were supplemented by *ex situ* maintenance of samples of species. More recent approaches apply a variety of tools and techniques as appropriate to a particular situation (**integrated** or **complementary** conservation).

New approaches emphasize that conservation is a dynamic process and nearly always requires some form of intervention or management. They acknowledge the dynamics of ecosystems, species and populations, and recognize the critical importance of questions of temporal and spatial scale. We have to consider just how variable they are in space and time: not only do species and their populations change in distribution and composition from year to year, as reviewed in Section 4, but ecosystems too are in a constant state of flux because of their inherent dynamics, as well as responding to changes in the local environment and climate (see Section 6). As a consequence vegetation may show dramatic changes over short periods of time, thus posing considerable challenges for conservation management. Moreover, the processes of succession in ecosystems are often cyclical and do not necessarily lead to identical results, so that the kind of community found may differ according to small changes in dynamics and processes. Do we want to conserve particular biological states or to preserve natural processes? Other questions posed are: Do we want to maintain the succession as such, or what stage, for instance, of vegetational development and composition do we wish to conserve – as it is today, as it was 10, 50, 100 years ago? Which species or combinations do we wish to retain? What form and degree of intervention is needed to achieve these results? How can the capacity of ecosystems to adapt to change be maintained? Section 13 includes a discussion of these issues.

In addition to the variable dynamics, we also have to take into account the range of different scales involved in conservation actions. Individual states are primarily concerned with biodiversity within their own frontiers but this has to be recognized as part of a global scene. A species that is rare in one country may be common in an adjacent one. Moreover, the very existence of a phenomenon may only be perceptible at a certain scale and so the scale at which biodiversity is studied may well affect our ability to perceive particular patterns or processes. As Noss and Harris (1986) have pointed out, conservation strategies are most effective when they address phenomena at multiple spatial scales and levels of organization (cf. also Noss 1990, 1992).

The new conservation paradigm also recognizes the important role of humans in biodiversity dynamics. One of the main problems of the 'hands-off' approach was that it failed to take into account the roles and requirements of local people, who were often excluded from protected areas despite the fact that the biodiversity in the reserve was often at least partially conserved and maintained by them. Modern conservation programmes now have multiple management objectives, and multiple-use reserves, with areas set aside for different purposes such as preservation or various levels of extraction. In some ways this approach

mirrors traditional practices. The continued need for integration of development and conservation is stressed throughout the GBA, and particularly in Section 13.

The threat of global climate change adds another dimension of concern for conservation planning. The effects of global change on ecological systems, species migration and survival, and on biodiversity in general, are difficult to predict because of our lack of understanding of the effects of greenhouse gases, direct human action, and many other factors on the way these systems function and the way in which species adapt. Despite the still considerable uncertainty as to the detail, it is widely agreed that the effects of climate change on ecosystems and their component species could well be significant and lead to major realignments and regroupings of species as has happened previously in the Earth's history (see Section 4.1). The possible impacts of global change on biodiversity and other scenarios for the future are considered in Section 11.4.

1.3.3.3 Improving the knowledge base

Throughout the Assessment, attention has been drawn to the large gaps in our knowledge in all areas and at all levels of biodiversity. As Sections 3 and 7 make clear, much of the basic inventory of biodiversity has not yet been undertaken, even at the level of species. But how do we set priorities for inventory programmes? Should we, for example, concentrate on certain poorly-known groups such as soil microorganisms, or should we focus our efforts more on surveying areas that are on the point of being converted to agriculture, or flooded to form dams? How can such long- and short-term goals be incorporated into a cohesive strategy?

Closely linked with inventory is the **monitoring** of biological diversity which is essential to provide feedback in adaptive management programmes. Monitoring – the repeated measurement of biological entities or processes over a time series – requires an adequate baseline inventory. Monitoring can be carried out over a range of different scales, from satellite monitoring of the whole planet to following demographic changes in individual populations of plants, animals or microorganisms. As discussed in Section 7, monitoring must therefore be clearly goal-orientated but at the same time should follow standardized procedures and statistical analyses so as to allow comparison with other studies, past and present. Careful planning, both logistical and financial is vital, and we need to ask questions such as: What are the techniques available? Are they cost-effective? How widely can they be applied? What have we achieved so far in these areas?

The rapidly accelerating generation of data about biodiversity, together with the vast amount of already accumulated information, risks overwhelming us if effective action is not taken to handle and co-ordinate it.

Thus, the study of biodiversity is heavily dependent on the rapidly developing field of information technology, and data and information management, which is discussed in Section 9. Appropriate data management is essential for linking the data obtained from inventorying and monitoring to the decision-making process. Yet, as Sections 2, 7 and 13 point out, the data we have at present, particularly at the taxonomic level, are highly diffuse, unevenly distributed with respect to their country of origin, and often difficult to access, partly because of the large number of disciplines that contribute and the wide variety of users, but also for historical reasons. Resolving this problem is a key issue when considering biodiversity. How can the data and information be made readily available and accessible to decision-makers, scientists and the general public? How can developing countries access the information they need in order to execute their national biodiversity programmes in line with the convention? How much effort and how many resources are needed, for example, to produce a global species list? What role will the global communication networks such as the Internet have in facilitating effective information flow? The issue of intellectual property rights, particularly with respect to recent controversies over the patenting of genetic information, has important implications in this context. These are among the issues reviewed in Sections 9, 10, 12 and particularly Section 13.

1.3.3.4 Human and institutional capacity

It is not just the data and information sources that are unevenly distributed. The human resources (e.g. scientists) and institutional resources (e.g. systematic reference collections, botanic gardens, genetic resource collections) for biodiversity understanding and management are also found largely outside the areas of greatest diversity. Are the facilities adequate even in the most well-developed countries? What are the options for redistributing some of these key resources? The extent and distribution of the resources are examined in Section 8, which also, together with Sections 7 and 13, asks what can be done to improve the situation.

1.3.3.5 Global and national co-ordination

The uneven distribution of resources and information, the difficulty of accessing information, the separation between the collectors and users of that information and the wide range of disciplines and perspectives involved in biodiversity make effective global and national co-ordination a priority for biodiversity management. More effective national and international organization of the knowledge we do possess would greatly enhance the effectiveness of the way in which we manage our planet's resources. An essential starting point is to look at biodiversity from a global perspective and assess what we

know, a process to which it is hoped the GBA will make a significant contribution.

EXECUTIVE SUMMARY

- The recognition and characterization of biodiversity depends critically on the work of three scientific disciplines. *Taxonomy* provides the reference system and depicts the pattern or tree of diversity for all organisms (Chapter 2.1). *Genetics* gives a direct knowledge of the gene variations found within and between species (Chapter 2.2). *Ecology* provides knowledge of the varied ecological systems in which taxonomic and genetic diversity is located, and of which it provides the functional components (Chapter 2.3).
- There appear to be no short cuts to full examination of biodiversity. All three disciplines report in this assessment that, having characterized only part of the world's biological diversity, it will be necessary to undertake similar work to survey the remainder. While predictions can be made, they are no substitute for full enumeration. It is in the nature of biodiversity that surprises and uniqueness abound: predictive methods, such as the use of indicator species, latitudinal gradients, and mapping of hotspots, are of limited value.
- Taxonomy provides the core reference system and knowledge-base on which all discussion of biodiversity hinges: the framework within which biodiversity is recognized and in which species diversity characterization occurs. The most commonly used units of biological diversity are *species*, the basic kinds of organisms.
- Taxonomic characterization of the world's organisms is a mammoth but essential strategic task with which only limited progress has been made: just 1.75 of the estimated 13 to 14 million species have so far been described, and most of these are still poorly known in biological terms. There is not even a comprehensive catalogue of these 1.75 million known species.
- Despite its universal usage as a basic unit of taxonomy, it is difficult to agree on an exact definition of what constitutes a species. As a result there is considerable variation in concept and usage which may be reflected in differing classifications and species totals.
- Taxonomists have the task of enumerating which species exist and placing them in a *taxonomic hierarchy*. This taxonomic hierarchy serves both as a classification used for reference purposes and as a summary of the evolutionary tree. It can also be used to predict properties of certain organisms. The hierarchy is characterized by observation of the patterns of resemblances in comparative features such as morphology, anatomy, chemistry (including molecular data), behaviour and life-history.
- Systematic and evolutionary studies provide valuable knowledge about the evolutionary origins and patterns of life, the scientific map of diversity. This is the map that must be used in planning conservation, prospecting, exploitation, regulation, and sustainable use.
- It is considered important that assessments used in the evaluation of resources and conservation options make adequate use of *taxic diversity* measures which take into account not just numbers of species but their taxonomic positions and the differing contributions that different species make. The map or tree of diversity is occupied by very varied densities of species: in some parts there are thousands of species, in others just one or two. It follows that the very few species in certain parts of the pattern are of exceptionally high scientific value.
- Genetic diversity is the diversity of the sets of genes carried by different organisms: it occurs not only on a small scale between organisms of the same population, but on a progressively larger scale between organisms in different populations of the same species, between closely related species such as those in the same genus, and between more distantly related species, those in different families, orders, kingdoms and domains. Genetic diversity may be characterized by a range of techniques: by observation of inherited genetic traits, by viewing under the microscope the chromosomes that carry the genes, and by reading the genetic information carried on the chromosomes using molecular techniques.
- Genes transmit features from one generation to the next, so determining by inheritance and in interaction with the environment, the pattern of variation realized in features

seen within and between species. Similarly alterations in the genes carried forward to future generations mark the path of evolution. Yet scientists observe that in neither case is there a strictly one-to-one relationship between genetic diversity and the realized diversity of organisms characterized by taxonomists.

- Genetic analysis, including molecular techniques, provides a formidable tool for gaining access to precise gene differences both within and between species. Within species genetic details can characterise the traits and the populations on which natural selection and the process of evolution is acting. Between closely related species gene comparisons can reveal details of speciation and colonization.
 - It is selection acting on genetic diversity that carries forward both ecological adaptation and microevolution: to limit or reduce the genetic diversity within a species is to limit or reduce its potential or actual role in the ecological and evolutionary development of the biosphere.
 - The food plants, animals, fungi and other micro-organisms on which all humankind depend arise from genetic variants of originally wild organisms. The genetic resources in both wild and domesticated organisms thus represent a patrimony of resources for future use. Even the present well-developed food crops and animal resources are constantly at risk because of the rapid adaptation of pests and diseases: skilful and extensive manipulation of genetic resources is needed even to maintain agricultural productivity.
 - Organisms are not evenly distributed: they occur in an intricate spatial mosaic, classified on a world scale into *biogeographic zones*, *biomes*, *ecoregions* and *oceanic realms*, and at a variety of smaller scales within *landscapes* into *ecosystems*, *communities* and *assemblages*.
 - In terrestrial systems the community found at any one point can be characterized by the physical environment (ecoregion), the physiognomic type (biome), and the floristic/faunistic (biogeographic) zone in which it occurs. In marine systems communities are characterized in terms of the physical environment and the faunistic (biogeographic) zone.
 - The units of classification used on a global scale differ in how they are recognised and consequently in the distinctions between their subdivisions. Biogeographic zones differ taxonomically in the flora and fauna present, even between areas of similar physical environment (e.g. within the same ecoregion) or similar physiognomy (e.g. within the same biome). Conversely, the physiognomic differences between biomes within one biogeographic zone are paralleled by those within another.
 - All existing global classifications of ecological systems are to some extent inadequate, either in their methodology or in their spatial coverage, or in both. A robust classification of the world's ecosystems which can be used to map the distribution of ecological resources is urgently needed.
 - The biodiversity within an area can be characterized by measures of *species richness*, *species diversity*, *taxic diversity* and *functional diversity* – each highlighting different perspectives.
 - (a) Species richness (also called α -diversity) measures the number of species within an area, giving equal weight to each species.
 - (b) Species diversity measures the species in an area, adjusting for both sampling effects and species abundance.
 - (c) Taxic diversity measures the taxonomic dispersion of species, thus emphasizing evolutionarily isolated species that contribute greatly to the assemblage of features or options.
 - (d) Functional diversity assesses the richness of functional features and interrelations in an area, identifying *food webs* along with *keystone species* and *guilds*, characterised by a variety of measures, strategies and spectra.
 - A serious limitation on all measures of species diversity in an ecosystem is our inability to survey all organisms at any site: only a few taxonomic groups are sufficiently known for complete field surveys to be made.
 - At the smaller scale, landscapes are composed of areas characterised as ecosystems or communities. The diversity between areas is measured as β -diversity, the change in species present.
 - *Systems diversity* is assessed as the richness of ecological systems in a region or landscape.
-

2.0 Introduction to the characterization of biodiversity

2.0.1 What is biodiversity?

As explained in Section 1, biodiversity means the variability among living organisms from all sources and the ecological systems of which they are a part; this includes diversity within species, between species and of ecosystems. Were life to occur on other planets, or living organisms to be rescued from fossils preserved millions of years ago, the concept could include these as well. It can be partitioned, so that we can talk of the biodiversity of a country, of an area, or of an ecosystem, of a group of organisms, or within a single species.

Biodiversity can be set in a time frame so that species extinctions, the disappearance of ecological associations, or the loss of genetic variants in an extant species can all be classed as losses of biodiversity. New elements of life – by mutation, by natural or artificial selection, by speciation or artificial breeding, by biotechnology, or by ecological manipulation – can similarly be viewed as additions to biodiversity.

2.0.2 What is meant by characterizing biodiversity?

The scientific characterization of biodiversity involves what may seem like two different processes, the observation and characterization of the main units of variation (e.g. genes, species and ecosystems), and the quantification of variation within and between them (genetic distance, taxonomic relatedness, etc.). In reality they are part of the same process: the analysis of pattern defines the units as well as characterizing their variation.

In each of the three chapters that follow an assessment is made both of the reference framework and units used, and of the methods for quantifying variation. Chapter 2.1 deals with the central issue of characterizing species or taxonomic diversity. Chapter 2.2 assesses genetic diversity that occurs both within and between species. Chapter 2.3 introduces the diversity of ecological systems in which this species and genetic diversity occurs, a theme further developed in Sections 5 and 6.

A number of techniques described here are of wide application both in characterizing diversity and in topics addressed in later sections. The molecular techniques described as part of genetic diversity (Chapter 2.2) are widely used in taxonomic analysis (2.1) and in biotechnology (Section 10). The taxic diversity measures described in 2.1 are increasingly of interest in the comparison of ecological systems (2.3). No attempt is made to appraise cultural diversity: with its human and cultural dimensions, this is left until Sections 11 and 12.

Lastly, we should comment that this assessment of characterization units and techniques leaves rather a dissected view of biodiversity at different levels of description. It is for other sections to assess our knowledge of how the system works as a whole.

2.1 Biodiversity from a taxonomic and evolutionary perspective

This chapter contains an introduction to the taxonomic and evolutionary characterization biodiversity (2.1.0–2.1.4). This is followed by an overview of the power and utility of taxonomic products in general biodiversity usage (2.1.5), and in the particular context of species diversity assessment (2.1.6).

2.1.0 Introduction: patterns of living organisms – classification and evolution

The study of the different kinds of living organisms, the variations among and between them, how they are distinguished one from another, and their patterns of relationship, is known as *taxonomy* or *biosystematics* (see Box 2.1-1 for strict definitions). Taxonomy is thus fundamental in providing the units and the pattern to humankind's notion of species diversity. Indeed, the first estimates of global biodiversity were those made by taxonomists.

At one end of the range of taxonomic studies are rather practical operations such as naming and cataloguing what kinds of organisms exist (including the preparation of checklists, plant Floras, animal handbooks, computerized identification tools, etc.), the information science aspect of taxonomy. At the other end are sophisticated studies of the branching tree and geographic patterns of evolution by descent (known as *phylogeny*) and taxonomic measures of biodiversity. Simple introductory texts are provided by Ross (1974), Jeffrey (1982), Heywood (1976) and Llorente-Bousquets (1990).

Despite the sometimes bewildering complexity of forms observed, biosystematists have succeeded in most major groups in recognizing the patterns of variation and occurrence that are observed. The patterns can be depicted graphically as nested hierarchies, boxes within boxes, or branching trees (Figure 2.1-1) which, as we shall see later, can be thought of either as a nested classification or as a tree of descent. This practice originated simply as a human method of organizing knowledge, as in Aristotle's principle of Logical Division (Turrill 1942), where organisms are divided into contrasted classes: A, not A; useful, not useful; woody, not woody. Similarly, in Diderot's *Encyclopédie* (Diderot 1751–65) all knowledge, including both biology and many other topics, is connected on a hierarchical tree printed inside the book's covers. But since the acceptance of Darwin's theory of evolution by descent with modification (Darwin 1859), the success of using a hierarchy is attributed to organisms having evolved by descent with modification through time, a process that produces a branching tree. The pattern of life actually is intrinsically tree-like and hierarchical in variation pattern.

At the lowest level of this hierarchy are individual organisms which live and die (e.g. a particular dog, a

Box 2.1-1: Definitions of taxonomy and biosystematics.*A distinction between taxonomy and biosystematics*

Taxonomy in the strict sense refers to all information science aspects of handling the different sets of organisms. The word is sometimes used in contexts outside biology so, strictly, one should speak of biological taxonomy. Mayr (1969) defines it thus:

Taxonomy is the theory and practice of classifying organisms.

It can be thought of as having four components (Bisby 1984; Abbott *et al.* 1985; Radford 1986; Hawksworth and Bisby 1988):

- (i) the classification
- (ii) the nomenclature
- (iii) circumscriptions or descriptions
- (iv) identification aids

Biosystematics is a broader topic, which includes taxonomy, but also includes the full breadth and richness of associated biological disciplines, including elements of evolution, phylogeny, population genetics and biogeography (Hawksworth and Bisby 1988; Quicke 1993). In the late 1930s the term systematics was used in Britain to emphasize the move away from classical taxonomy, as in the phrase 'The New Systematics', and the establishment of 'The Systematics Association'. Simpson (1961) and Mayr (1969) define it thus:

Systematics is the scientific study of the kinds and diversity of organisms and of any and all relationships among them.

Again the word is used in non-biological contexts: biosystematics makes clear the biological context.

particular tree, a particular bacterium). Individuals occur usually as members of more-or-less continuously existing *populations*, which can be variously characterized, depending on their *breeding systems*, either as being related by the process of mating amongst their immediate ancestors (as among humans, among beetles and among palm trees), or as having a common descent from a single recent ancestor (as in the HIV virus). These populations themselves fall into patterns, some being clearly similar and of the same *species*, others being different to varying degrees and thus of different species e.g. species of rats: Norway rat (*Rattus norvegicus*), roof rat (*Rattus rattus*); species of *Prunus*: plum, cherry, peach, apricot; species of large cats: lion, jaguar, leopard, tiger. Even though the exact definition of a species is a matter for debate, the species is used universally as the basic category of the classification.

As the common names sometimes imply, some species are clearly members of recognizable larger aggregations (or the descendants of a common ancestral form) known as *genera* (singular, *genus*): e.g. date palm, canary date palm, dwarf date palm – species in the date palm genus *Phoenix*. This process of aggregating similar or related forms can be continued to form larger aggregations. Genera are

aggregated into *families*, families into *orders*, and so on up the hierarchy as shown in Table 2.1-1. The higher categories of the hierarchy, such as families and orders, are vitally important for communication; they permit discussion, generalization and information retrieval about particular sets of organisms. The overall result is a hierarchical classification going the whole way from species (or even *subspecies*, or human-made varieties called *cultivars* or *breeds*, within species) up to the major *kingdoms* such as plants, animals and fungi.

To give some idea of our progress in understanding life on Earth a comprehensive, detailed classification of living organisms on earth compiled into a single work (Parker 1982) recognizes 4 kingdoms, 64 phyla, 146 classes, 869 orders and about 7000 families. However, recent advances in the study of cell organelles and DNA sequences have led to rapid changes in the topmost categories: Whittaker (1969) and Margulis and Schwartz (1982) propose five kingdoms and Woese (1994) places three domains above the kingdoms (as depicted in Figure 2.1-5). The total of 1.75 million species thought to have been described to the present day represents a small fraction of the 13 to 14 million species estimated to exist in total. There is at present no comprehensive catalogue even of these 1.75

Figure 2.1-1: Three graphical representations of the taxonomic hierarchy of some members of the Rosaceae: (a) nested hierarchy; (b) box-within-box, and (c) a branching tree.

million species (see Chapter 3.1 for further discussion and Tables 3.1.2-1 and 3.1.2-2 for species counts).

Two properties of the taxonomic hierarchy are pivotal to its value in characterizing species diversity. First, the hierarchy provides a reference system that permits the summary, storage and retrieval of information about all organisms (Simpson 1961; Blackwelder 1967; Mayr 1969; Farris 1979; Bisby 1984). Secondly, the hierarchy attempts to be natural, by reflecting the presumed pathway of evolution and the pattern of resemblances among the organisms (Darwin 1859; Haeckel 1866; Cain 1954; Simpson 1961; Mayr 1963; Davis and Heywood 1963; Hennig 1966).

2.1.0.1 Folk classifications and the origin of scientific taxonomy

Throughout history humans have classified organisms. We use our innate classificatory abilities every day: we eat rice

in quantity but not peppercorns. In supermarkets many foods are arranged by species. All human societies have *folk taxonomies* – traditional classifications of organisms often associated with cultural, survival and culinary practices (Berlin 1992). The Inuit of East Hudson Bay recognize two major kinds of animals, *umajuq* which are game animals, and *umajuquti* which are domestic ones (Atran 1990). The Tzeltal Indians of Chiapas, Mexico, use four life-forms – trees, herbs, grasses and vines (Table 2.1-2; Berlin *et al.* 1974), a system which contains logical structures (generic taxa) analogous to the genus and species of scientific taxonomy.

It is from these folk classifications that scientific taxonomy emerged, initially in Europe, bringing together the more formalized cataloguing of medicinal herbs, world-wide collecting expeditions, particularly by the seafaring nations, and the dawn of scientific discovery in biology. Mediaeval herbals contained descriptions of herbal extracts

Table 2.1-1: Major taxonomic categories.

Categories (in descending rank)		Examples	
Informal category above kingdom			
Domain	Eucarya	Eucarya	Eucarya
Formal categories recognized			
Kingdom*	Animalia	Plantae	Protoctista
Phylum (Division)*	Chordata	Tracheophyta	Ciliophora
Class (Super-, Sub-)*	Mammalia	Angiospermae	Oligohymenophora
Order (Super-, Sub-)*	Primates	Fabales	Hymenostomatida
Family (Super-, Sub-)*	Hominidae	Leguminosae	Parameciidae
Tribe (Super-, Sub-)*	Hominini	Vicieae	–
Genus (Super-, Sub-)*	<i>Homo</i>	<i>Pisum</i>	<i>Paramecium</i>
Section (Sub-)*	–	–	–
Species (Super-, Sub-)*	<i>Homo sapiens</i>	<i>Pisum sativum</i>	<i>Paramecium caudatum</i>
Variety (also Form)	–	<i>P. sativum</i> var. <i>sativum</i>	–

Ambiguous taxa	18
Total	471

and crude illustrations of the plants from which they came, often with a number of animal extracts and even inanimate items alongside. The thoughtless copying of such works and the attempts to shoe-horn into them new discoveries from all over the world soon led to chaos. It was against this background that the cataloguing energies of the eighteenth century Swedish naturalist Carl Linnaeus, and the first attempts at natural classification by the French naturalists, were so badly needed.

For a long time species were named using a descriptive Latin phrase, but no formal system was widespread. It was Linnaeus who adopted the binomial system in later editions of his master catalogues *Systema Naturae* (Linnaeus 1735) and *Species Plantarum* (Linnaeus 1753), and a system of nomenclature broadly similar to his has continued to the present day. It is now formally embodied in the various

2. Fungi are covered by the ICBN/as are Cyanobacteria and certain Protozoa.

international rules for nomenclature and almost universally endorsed as the *scientific names* of organisms. Starting in the same period, much of the classification that we use today was put in place by de Jussieu, Adanson, Cuvier, Lamarck and Geoffroy Saint-Hilaire. It was they who recognized the major natural groupings of animals and plants, albeit without Darwin’s insights into evolution or today’s understanding of phylogenetic taxonomy. The classification and nomenclature system has developed continuously from that time and now enables workers in all sorts of professions from all over the world to communicate reasonably effectively about the same organisms, be they plants, animals, fungi or other microorganisms.

2.1.1 The basics of taxonomic characterization: what taxonomists do

There are common elements to nearly all taxonomic studies despite the different practices relevant to different groups of organisms (Blackwelder 1967; Davis and Heywood 1963). Most studies start from the examination of live or preserved specimens, either because newly discovered specimens do not fit the known patterns, or because specimens are being re-examined to solve a problem in the existing taxonomy. Some specimens are found to belong to already-known species. They are identified and the data associated with the specimen are added to the documentation for the species, possibly adding new localities, or variations in the description. Others prove to be of a previously unnamed organism. After careful research in the literature, and thorough examination of the new taxon, a new species, subspecies or variety is described and named using the international codes of nomenclature (see Table 2.1-3).

Ideally most taxonomic studies would be *revisions* of an entire group of organisms over its complete geographical range – a whole genus, family or order – but this is difficult to achieve both because of the labour involved and because

of the logistics needed to see specimens or cultures and study the organisms over several continents. Depending on the size of the group and its distribution, it may take anything from three to ten years of full-time work, in extreme cases even a lifetime, for a taxonomist to complete. The advantage is that all species can be examined in a comparable way, and that if all have been examined, decisions and descriptions of genera and families will not be confounded by intermediate or more extreme species missed out of the study. Such studies involve examining all available specimens, often by loans from the major collections supplemented by local and specialist collections, followed by the publication of a clear summary of the taxa. It is also important to ascertain the correct name for each taxon plus synonyms where they occur.

2.1.1.1 The role of specimens in taxonomy

Collections of biological specimens serve several distinct fundamental functions in the characterization of biodiversity. One of these, discussed here, is as the raw material for taxonomy: all taxonomic research is based on the comparison of large numbers of specimens. Equally important for biodiversity survey and inventory is the use of these same collections of specimens as the raw data for biological recording, discussed in Section 7: the time, the place, and the species for each biodiversity data point come from one of these specimens. We thus think of the collections of living and preserved specimens as fundamental resources for biodiversity assessment world-wide, the subject of Chapter 3.2. A third, specialist, usage is for so-called *type specimens* used to fix the application of names to organisms, discussed in 2.1.1.2.

The specimens needed by taxonomists cover a very wide range: preserved specimens in museums and herbaria; living specimens in zoos, aquaria, botanic gardens, arboreta, germplasm banks and culture collections; and associated data such as descriptions, illustrations, chemical

Figure 2.1-2: Comparative data in systematics: (a) gross morphological features in pine trees (*Pinus*, Morin *et al.* 1993), (b) microscopic features of genitalia in bumble bees (*Bombus*, Alford 1975), (c) oscillograms of grasshopper calling songs (*Enchorthippus*, Ragge and Reynolds 1984), and (d) 18S ribosomal DNA sequences (from the V4 hypervariable region) in flagellates (*Paraphysomonas imperforata*, *P. butcheri*, *P. vestita* and *P. foraminifera*, Accession Nos. Z29680, Z29679, Z28335 & Z33646 in the EMBL Sequence Data Library, communicated by J. Rice, 1995).

records, sound recordings and genome sequences stored in libraries, film and tape archives and computer databases. There is a need to marshal large numbers of specimens from the full geographical range side by side for comparison, and to document and preserve evidence of diversity with specimens providing fixed data points.

Taxonomists need to see the widest possible range of specimens for the group of organisms under study. A full geographical and ecological range, plus specimens of differing life stages and temporal variations are needed: juveniles and adults, vegetative and reproductive, male and female, winter and summer plumage, larvae, pupae and adults, seeds, eggs or spores as appropriate to the organism. The specimens used for accessing these vary from entire populations (e.g. a bacterial culture), to individual plants or animals (e.g. a pressed plant or a pinned insect), to fragments such as fruits, skulls, skins or blood samples. Associated data sets such as DNA sequences, oscillograms of animal calls and behavioural recordings may be relevant too. Some different data types are illustrated in Figure 2.1-2.

Ideally the data used for studying each group of organisms will span an immense range of characteristics drawn from different organs, different life stages and different aspects of the biology (see Figure 2.1-2). It is the morphology (physical shape and structure of the organism) and the anatomy (shape and structure of internal organs) that are most easily available and consequently most widely used. Even microscopic details, e.g. of insect genitalia or of fungal spore sculpturing, are often well preserved. Modern techniques such as electron microscopy, phytochemical analyses and DNA sequencing can often be applied to specimens of all ages.

Taxonomic research increasingly involves substantial work in the field to study the living organism *in situ*, or to establish living collections in a laboratory setting. This is an opportunity to collect data that cannot be obtained from preserved specimens, such as physiological measurements. Behaviours such as feeding or food plant preferences, locomotory patterns, microhabitat preferences, timing of sexual or other biological activity (phenology, diurnality

versus nocturnality, migration, circadian rhythms in depth for oceanic plankton), can all contribute to a systematic study. Many species build burrows, nests, brood chambers, retreats, webs, moulting chambers, egg-sacs, and other such constructs. Where these behaviours reflect heritable variation they provide valuable sources of systematic data revealing patterns of variation comparable to those in morphology and anatomy. Samples destined for gene sequencing, particular forms of anatomical comparison, or chemical analysis may require special techniques of preservation. Videotapes of behaviour or audiotapes of calls are obtainable only through fieldwork and must be stored and preserved in special repositories.

Each specimen collected in the field and deposited in one of the public collections is of potential value far beyond the particular study or programme for which it was collected. There is a consequent responsibility on the collector to establish without doubt the minimum parameters: location (increasingly giving precise latitude and longitude using a global positioning device), altitude or depth, date of collection and an identifying unique collector's name and number. Other valuable data are items that cannot be derived from the specimen at a later date – such as substrate, odour, sounds, colours (which often fade), behaviours, and position on a host. Maximum benefit will be obtained if, possibly after immediate usages, every specimen is deposited in a public collection where it can be used many times to contribute to biodiversity knowledge: the resources thus generated are reviewed in Chapter 3.2. For the system of specimen usage to work well amongst taxonomists it is important that at least one duplicate of each specimen, or the single specimen itself, be deposited at a public collection in the country of origin (this is usually a condition of collecting permits), and that such collections should make the specimens available for loan to taxonomists.

2.1.1.2 Stability of scientific names

The object of scientific nomenclature is to provide a stable unique name for each organism (Jeffrey 1989). The usage and giving of names is governed by the various international codes of nomenclature which, for historical and biological reasons, are slightly different for certain major groups of organisms (Table 2.1-3). All of the codes provide a mechanism for publishing a new name for a newly recognized taxon, for fixing a name to a particular organism by citing a *type*, and for arbitrating between synonyms where a taxon has accidentally been named more than once, or where two taxa have been united into one. The type of a species name is a particular cited specimen in a particular collection, the *type specimen*. The continued preservation of type specimens in public collections is important so that subsequent checks can be made that the right name is being applied to the right organism.

In many cases the giving of names has proved to be a troublesome business (Quicke 1993). On the one hand it is essential that taxonomists continue to map the pattern of variation and descent: this leads to changes in the classification and consequent changes of names, an inevitable price to pay for progress. We do need these changes if modern data and new discoveries are to be incorporated into our view of the taxonomy. More troubling, however, are cases of seemingly unnecessary name changes arising from different interpretations of the rules, or the continual discovery of older names that take priority under some of the codes. Recent discussions have started a move to eliminate such nomenclatural changes, either by permitting certain names to be conserved, or by listing names in current usage and protecting them from the priority of older names (Hawksworth 1991, 1992).

Some problems arise from the existence of different codes for different groups of organisms. Certain organisms, such as the blue-green algae, have even been treated variably under one code or another, leading to ambiguity or duplication (Table 2.1-3). There are also cases of organisms under different codes being given the same name: the names must be unique but only within the domain of one code. Steps are being taken to harmonize the existing codes and a working body of IUBS is now discussing the difficult task of preparing a unified code for all organisms (Hawksworth 1994; Hawksworth *et al.* 1994).

Common or vernacular names, although often used very precisely in a given community, are usually neither unique nor universal. The problem is a tendency to re-use common names for wholly or slightly different organisms as human communities, colonial powers and languages have moved from one place to another. The names *raetam* and *retama*, for instance, cover a wide range of plant species in Arabic-, Spanish- and Portuguese-speaking countries.

2.1.2 Characterizing flora, fauna and microbiota:
preparing Floras, handbooks and keys

One of the main tasks of taxonomy is to characterize the species of plants, animals and microorganisms so that they can be recognized, used and studied by others. With the exception of the orally communicated folk taxonomies of indigenous peoples, biologists all over the world have, since the eighteenth century, drawn their knowledge on species characterization from the primary catalogues created by the fieldwork and research of an international community of taxonomists. Key elements in these primary works are (1) the classification (what species and higher taxa exist), (2) the nomenclature (unique scientific names for the species and higher taxa), (3) descriptions of the organisms in these species and higher taxa, and (4) identification aids (with which to identify to which species and higher taxon a freshly encountered specimen belongs). Linnaeus called his primary catalogue a *Systema Naturae*

(Linnaeus 1753) and recent electronic publications use phrases such as Species Diversity Information System (e.g. the ILDIS *LegumeLine* database, Zarucchi *et al.* 1994; Bisby *et al.* 1994) and Expert Identification Systems (e.g. the ETI CD-ROM *Linnaeus Protist*, *Lobsters of the World*, Estep *et al.* 1992; Estep and Rey 1993; Holthius 1994): but the majority are published books called Floras, Faunas, Monographs, Catalogues, Checklists, Handbooks or Keys.

Vascular plant primary catalogues fall into two classes: Floras and monographs. Floras document all of the higher plants in a given land area, such as local Floras, national Floras and regional Floras. National Floras exist for quite a large set of nations (see Frodin (1984) for coverage) and regional Floras have been completed for the former USSR (Komarov *et al.* 1934–60), for Europe (Tutin *et al.* 1964–80) and for West Tropical Africa (Hutchinson and Dalziel 1927–36). Projects are in progress for some other regions (e.g. *Flora of North America*, Morin 1993 *et seq.*; *Flora Malesiana*, van Steenis 1948 *et seq.*) but for many species-rich tropical areas there is still no effective inventory. Botanical monographs document all plants in a given higher taxon world-wide or in a region, as in generic and family monographs.

In practice the study of a major taxon world-wide is often not practicable, so there are few world-wide monographs, mostly of genera, and rather more regional monographs of genera or families. Again, there are no recent monographs of the large or tropical plant families.

For animals, the pattern is much less tidy, and for good reason! The equivalent to the plant scene would be Faunas (all animals of an area) and monographs (all animals in a group, world-wide). But there are so many more animal species, and they belong to widely different groups, each of which may have its own discipline of specialists, such as entomologists, herpetologists, ornithologists, lepidopterists, etc. Most descriptive works are restricted to a single higher taxon and are variously local, national or occasionally regional in scope. The result is an even more patchy coverage than is found in plants with not only some overlaps, but very, very large gaps: many major groups are uncatalogued for large parts of the world. Even the best-covered countries (in Western Europe and North America) have far from complete coverage of all animal groups. Standing way above the other problems is the difficulty in cataloguing insects (over 950 000 world-wide Wilson 1992), of which the beetles, Coleoptera, dominate with 290 000 species. Where Fauna projects have been undertaken, as in the *Faune de France* (FFSSN 1921–66), the work is always segmented into different volumes researched by different authors. There are rather few guides to the coverage of the world's animals: notable are Sims and Hollis (1980), *Animal Identification* in three volumes covering marine and brackish water animals (Vol. 1), land and freshwater animals excluding insects

(Vol. 2) and insects (Vol. 3), and *Key Works for Northwestern Europe* (Sims *et al.* 1988).

Lastly – what is the level of treatment of the other major groups, such as marine and lower plants, marine animals, fungi, bacteria and the viruses? There are some groups that are partially covered: the bryophytes, mosses and liverworts (rather few species and reasonably accessible to field botanists), fish (of economic importance), some bacteria (of medical importance) and some fungal groups (of economic importance). For most of the rest, coverage is sparse indeed: few coherent catalogues exist even for the many species known to taxonomists, let alone the vast numbers of species yet to be discovered.

2.1.2.1 The amount of research work involved

The type and amount of research needed to create one of these primary works varies enormously, particularly with how many species are to be covered, whether the group of organisms is well or poorly known, and how well explored is the region to be covered. For poorly-known groups and little-explored areas, years of field exploration may be needed both to accumulate sufficient specimens of each species encountered and to increase the chances that all species in the area have been encountered. Conversely, for well-known groups and much-explored areas there may already be a plethora of material lodged in museums or herbaria: the problems relate more to seeing all this material (borrowing it or visiting it), and to sorting out conflicts in existing taxonomic treatments of the organisms. Depending on how full a treatment is prepared, and particularly on whether all four elements are represented (classification, nomenclature, description and keys), the creator of the work will need to pass the following milestones:

1. Form a concept of the exact set of species being treated, often involving decisions on:
 - what are the species: how are they delimited, how are problems of apparent overlap, intermediacy, hybridization and discontinuity dealt with;
 - how are these species classified, either within the existing published classification, by extending the classification, by adjudicating between alternative views, or by creating a new classification.
2. Form an opinion on the correct (or new) name for each species and each higher taxon, and on the names and taxa from other treatments to be placed in synonymy.
3. Create a description of each species by studying the range of variation within that species as evidenced by field observations or by examining preserved specimens. The range of variability in one area may be greater or

Figure 2.1-3: (a) Annual rates of production of the major regional Floras (Polhill 1990).

Flora	Started	First issue	Species published	Total	%	Species/year	Actual or projected completion

(b) Total number of species treatments published in major regional Floras, in five-year intervals (Polhill 1990).

less than that recorded in other works for other areas. Additional descriptive features such as illustrations, distribution maps, ecological features, etc. may be added as well.

4. Create an identification key that leads unambiguously to an identification for freshly encountered specimens. Where possible easily visible, clearly demarcated characters should be used.

To give some idea of the amount of work involved, we cite the successful completion of *Flora Europaea* (Tutin *et al.* 1964–80). Its five volumes, containing a medium (synoptic) rather than full treatment of 11 557 plant species from the well-known, well-collected flora of Europe took 25 years work for a network of full- and part-time specialists to complete. But progress is much slower in the tropical regional Floras where more original research and fieldwork is needed, as illustrated in Polhill’s (1990) comparison of nine regional Floras summarized in Figure 2.1–3 *a* and *b*.

Floras, Faunas, monographs, many handbooks, and guides all tend to contain all four elements – classification, nomenclature, descriptions and keys. However, there can be substantial variations in how complete the descriptions are, whether voucher specimens are cited, whether illustrations and maps are included and in the extent of additional ecological, behavioural or economic information given. Checklists normally contain the classification and nomenclature of species, but accompanied by just a geographical distribution – no descriptions or identification aids. They are produced either as quicker projects, or to cover a wider geographical or taxonomic range than could otherwise be contemplated for full treatment. Keys are sometimes published alone, as a preliminary to fuller treatment, as companions to existing works, or to resolve urgent needs for identification in economic or medical contexts.

2.1.2.2 Modern developments: databases and expert identification systems

This is written at a time of unprecedented change in the technology and dissemination of primary and other taxonomic works. Information technology is rapidly

bringing in electronic communication amongst dispersed taxonomic contributors working as teams, the creation of major taxonomic works as databases, and the electronic dissemination of information to users by communications networks such as Internet or by CD-ROM disks. Some of the electronic products are simply electronic versions or compilations from existing primary works, but increasingly major primary projects are being compiled in this way: for instance the ICLARM/FAO FishBase international project on fish (Lourdes *et al.* 1994; Froese and Pauly 1994) incorporates the primary database on fish genera and species (Eschmeyer 1990, 1992), and the ILDIS species diversity system on legume plants is based on a fresh synthesis of the species taxonomy of Leguminosae by a world-wide network of experts (Zarucchi *et al.* 1994; Bisby *et al.* 1994).

A particularly important development is the bringing together of two technologies, the use of descriptive data tables in computer identification routines (Pankhurst 1975, 1978, 1991; Dallwitz 1974, 1980), and the facilities in modern computing environments to use windows containing diagrams, illustrations, photographs and maps. The resulting expert identification systems such as those produced by the Dallwitz school using the DELTA format (*Beetle Larvae of the World*, Lawrence *et al.* 1994; *Families of Flowering Plants*, Watson and Dallwitz 1994) and by ETI, the Expert Centre for Taxonomic Identification (*Linnaeus Protist*, Estep and Ray 1993; *Lobsters of the World*, Holthius 1994) are surely the sign of things to come.

Electronic means are also opening up the possibility of creating master catalogues both of larger and larger groups, and eventually of all known organisms. The IOPI World Plant Checklist (Burnett 1993; Bisby *et al.* 1993) and the BIOTA Terrestrial Arthropods projects (Hodges and Thompson, in press), for instance, propose to list all plants and all terrestrial arthropods. Very many groups of organisms now have rapidly progressing master catalogue systems (Bisby 1993, 1994) and the Species 2000 program of IUBS, CODATA and IUMS is proposing that many of these create a federated system which could lead to an index of all of the world's known organisms.

2.1.3 Characterizing systematic patterns: the species, their evolution and their classification

With the publication of Darwin's *On the Origin of Species...* in 1859, a major change was initiated in the way that the hierarchy of life was understood. Darwin's theory of evolution made sense of the natural patterns observed in the variation between organisms. Evolution occurs when organisms experience genetic mutations or recombinations, or when gene frequencies in populations change because of differing rates of reproduction or mortality. Through natural selection or genetic drift these heritable changes may spread throughout the population and over time can

lead to the production of new lineages closely similar to their relatives but differing by the possession of one or more new features (Ridley 1985, 1993; Futuyma 1987; Skelton 1993). If this new lineage continues to diversify throughout evolutionary time-spans, a wholly new higher taxon (lineage or clade) comes into being. Such lineage diversification produces a strictly hierarchical pattern. The roughly 4.5 billion years of biotic evolution has led to an enormous diversity of living forms on Earth. These forms can be grouped as sets within sets (a nested, hierarchical pattern) based on how recently they shared a common ancestor.

Darwin's observations of selective breeding and the way in which characteristics could be inherited, coupled with the immense diversity of different forms, for example of the birds and reptiles he saw on his voyage to the Galapagos, suggested to him that heritable differences between individuals could build up to produce new species and consequently higher taxa over long periods of time. Darwin himself was unaware of the mechanisms of genetics, but later studies have revealed how characters are heritable and mutable. Genetic mutation and recombination can each produce heritable novel characters which either by the process of natural selection or by non-selected random genetic drift lead to populations in different places diverging from one another over time (refer to Chapters 4.2 and 4.3).

Thus the products of evolution are arrayed in natural groups which all people, to a greater or lesser extent, can recognize. The evolutionary explanation of this pattern and diversity is the most important rationale for the taxonomic system used by scientists. This arrangement of the diversity of forms of organisms into a hierarchy serves our goals of communication, and information storage and retrieval, by reflecting the evolutionary process that created these forms in the first place.

2.1.3.1 Analysing systematic data to reconstruct evolutionary history

The results of the evolutionary process described above can be reconstructed by careful comparative study of the taxa involved (Hennig 1966; Eldredge and Cracraft 1980; Wiley 1981; Crisci 1983; Forey *et al.* 1992). Evolutionary mutation results in one of three patterns: new features arise, old features are lost, or pre-existing features are transformed to a greater or lesser extent. Any of these patterns are evolutionary changes. In practice, taxonomists find such heritable changes at all levels of the taxonomic hierarchy and at all levels of organismic organization, from single changes in DNA sequences to large changes in skeletal organization or even the entire body plan of the organism.

Because descendants inherit the features of their ancestors, a new mutation that first appeared in the ancestor

tends to be passed to its descendants. The set of all organisms, living and dead, that descended from that original modified ancestor is known as a lineage or clade. The novel mutation is known as a character, trait or feature. The old version of the trait is termed primitive, and the new version is derived. Over immense spans of geological time, speciation may occur so that the lineage splits into several to many species. Subsequently mutations may occur that delimit subsidiary lineages. From a strictly taxonomic point of view, why these changes occur, or whether they are beneficial, neutral or even detrimental to the species in which they occurred is irrelevant. What matters is that any given group of taxa both agree and differ in which characters they possess. Thus spiders are the only Arachnids that have terminal abdominal spinnerets and thoracic poison glands that open through the fang. On the other hand, only some spiders can make viscid, sticky silk; the webs of other species are dry. The simplest hypothesis is that the common ancestor of all spiders had spinnerets and fangs, but that only the common ancestor of a particular subset of spiders made viscid silk. For this simple case it is easy to see how important events in evolutionary history are reconstructed. The evolution of poison fangs and spinnerets marks the origin of spiders, and the invention of viscid silk marks the origin of a particular subfamily of spiders, the Araneoidea.

In evolutionary theory, characters of organisms that are similar because of inheritance from a common ancestor are called homologies. Classic examples are the wings or feathers of birds. No other group has feathers, and close examination of any feather discloses additional complex similarities that substantiate the homology of feathers. Another example is the sting of a wasp, actually the modified female ovipositor. Only some Hymenopteran species have stings, and in all of these species the sting is always the modified female ovipositor.

If evolution consisted only of the gain of complex homologies that were never lost by descendants, reconstructing evolutionary history would be simple indeed. Two processes complicate the issue. First, natural selection is amazingly efficient at moulding what appears to be the same feature from different starting points, a phenomenon termed evolutionary convergence. The wings of birds and bats are so similar that many years ago the homology of the two features was an open question. Detailed comparison, however, revealed substantial differences. The fleshy, spiny stems of some African *Euphorbia* plants are convergent on those of New World cacti. Porpoises are mammals, not fish, despite their fins. However, often the only way to test if two features are convergent or truly homologous is through quantitative analysis.

The second process that complicates systematic analysis is loss of features. Snakes originally had two pairs of limbs like other terrestrial vertebrates, but most have lost all trace of

Figure 2.1-4: A simple data matrix and the implied phylogenetic hypothesis of four taxonomic groups.

them. Fleas may not have wings, but many other features betray their relation to winged insects. Once again, it is frequently impossible to distinguish secondary loss of features from primitive absence except through quantitative analysis.

In practice, systematic data are compiled as a matrix of characters by taxa and analysed quantitatively by computer. By reading across (or down) the matrix, one can either read off all the relevant characters of a particular taxon, or conversely see which of a number of taxa possess a particular feature. The computer analysis is designed to provide the best possible estimate of the phylogeny of the group (as described above), expressed as a branching diagram or evolutionary tree. Such diagrams are often called trees, phylograms, dendrograms, or cladograms (because they indicate relationships between clades of organisms). For simple examples of straightforward data, the best estimate of the phylogeny is often obvious (Figure 2.1-4), but for larger numbers of taxa and characters, computer algorithms are used to produce estimates (Kitching 1992). A number of different algorithms are currently available (e.g. parsimony, maximum likelihood, or neighbour-joining techniques), and the subject of which provides the best estimate under what circumstances is an area of very active research (Swofford and Olsen 1990).

2.1.3.2 From phylogenetic trees to formal classifications

The trees that result from comparing characters in species are usually thought to be a graphic representation of the evolutionary relatedness of the taxa. These trees should be viewed as relative statements of relationship. For example, in Box 2.1-2 the wolf and the fox are hypothesized to share a more recent common ancestor with one another than with the cat, but the cat, wolf and fox all share a more recent common ancestor with one another than with the hoofed mammals such as cow and horse: the tree, therefore, shows a hierarchy of relationships. A tree does not explicitly hypothesize ancestor–descendant relationships. For example, the tree hypothesizes that wolf and fox are related, but not that wolves evolved from foxes or that foxes evolved from wolves.

One of the tasks of a taxonomist is to convert this graphic representation of relationship into the formal hierarchical classification of taxonomic categories such as genus, family, order, etc. In converting the tree to a classification, the systematist gives groups that share a common ancestor the formal taxonomic names. Such groups are called *monophyletic taxa* and they are

recognized because they share unique derived characters. The tree shows several sets of most closely related taxa that are nested within larger sets that contain additional taxa. These larger groups are, in turn, nested within even larger groups. By this process the phylogenetic tree is transformed into the taxonomic hierarchy used as a classification. In creating categories, systematists choose sets that naturally reflect the hierarchy inherent in the tree.

Despite the utility of the traditional taxonomic hierarchy in summarizing diversity and evolutionary relatedness, there are real problems in incorporating elements of the phylogeny into the hierarchy in a precise way. The difficulties relate to the subjectivity in deciding taxonomic rank, and the fact that phylogenies often imply hierarchies with more levels and greater asymmetry than is allowed in the taxonomic hierarchy. A simple example given in Box 2.1-3 makes this clear.

Some biologists (lumpers) stress similarities held in common by the organisms being studied and so tend to group several species into a single genus as in Box 2.1-3 (a). Others (splitters) stress differences between the species and so tend to divide the species into several different genera (Corliss 1976) as in Box 2.1-3 (d).

As a group of species is studied in more detail, it is not uncommon for it to be ever more finely subdivided or for the group as a whole to be elevated to a higher taxonomic category. This simply reflects the fact that detailed study uncovers more characters that emphasize the differences among the species. Microsporidia, which comprise a unique group of obligate, intracellular parasitic protists, are such a group now receiving increased taxonomic attention. Until recently, their ubiquity did not cause a threat to humans and few systematists worked to describe and classify the species. But since 1985, physicians have documented an unusual rise in worldwide infections in AIDS patients caused by four genera (*Encephalitozoon*, *Nosema*, *Pleistophora* and *Enterocytozoon*), and identifying microsporidian species is impeding diagnosis and effective treatment of patients. As a result, research has been focused on the group and the number and diversity of forms observed have risen sharply.

2.1.3.3 Why do classification schemes change?

Scientists working in genetic resources, biotechnology, agriculture, conservation and other disciplines that use existing classifications are often disconcerted to find that systematists change the classification scheme. These changes are, however, just the logical consequences of discovery of new data and new taxa, and correction of two kinds of mistaken interpretation.

New technologies constantly give rise to new sources of character information. New information reveals new similarities and differences among taxa that cause us to revise the placement of a taxon in a tree, or to choose to

Box 2.1-3: A phylogenetic tree which shows relative relatedness between ten species (A–J).

In this tree, **A** and **B** share a common ancestor and so are called sister taxa. Examining this tree you see that **D** and **E**, **F** and **G**, and **I** and **J** are also sister taxa. The sister group to species **C** is the group **A + B**, and so forth. There are several different ways to sort these species into acceptable, monophyletic genera, shown below. For example, the decision to place taxon **C** as one of many species in a genus (*a*) or as a single species in its own genus (*d*) is an artificial decision based on the personal preference of the taxonomist.

lump or split a taxon within an existing classification. An example of this sort of change is illustrated dramatically by the revision of prokaryote classifications resulting from molecular genetic data that have become available only within the past decade (Figure 2.1-5).

The discovery of previously unknown species will also change classifications. If unique, these species will have to have new taxa created for them. In addition, they have new characters or new combinations of characters whose study revises our hypotheses about evolutionary relationships of all the taxa. There have been some recent spectacular discoveries of new vertebrates such as the plankton-feeding megamouth shark described in 1983, the Vu Quang antelope of Southeast Asia in 1993, and the golden bamboo lemur (*Hap Alemur aureus*) from Madagascar in 1986. But

this is only the tip of the iceberg. Many more new species (especially microscopic organisms) are waiting to be discovered. Indeed, we cannot presently say how many species exist on Earth and some people’s estimates range over an order of magnitude, from 5 to 80 million species. For most species that have been documented, relatively little is known about their historical relationships, biological characteristics, or distributions within the Earth’s habitats and ecosystems.

The first common sort of interpretative mistake that bedevils systematic analysis is the discovery that the defining features of a taxon are convergent rather than homologous (see 2.1.3.1). The taxon then is known to be *polyphyletic* (the taxa do not share a recent common ancestor but instead the group has been defined by a

Figure 2.1-5: Fundamentally different views of the taxonomy of life based on (a) gross morphology (two kingdoms as reconstructed by Whittaker 1969), (b) cell structure and organelles (five kingdoms, Whittaker 1969) and (c) DNA sequence data (three domains, Woese 1994).

superficial similarity that does not indicate evolutionary relatedness). When this happens, the polyphyletic groups are abandoned and several monophyletic taxa are created in its place. For example, in Figure 2.1-4, the evidence of character 1 conflicts with that of 2 and 3. Either characters 2 and 3 are homologous and 1 is convergent, or the reverse. If scientists did not know of characters 2 and 3, but only of 1 and 4–7, the evidence of character 1 would group the cat with the wolf to the exclusion of the fox. Hence discovery of characters distributed as 2 and 3 can change phylogenetic hypotheses. In practice, most systematists do not change official classifications until the new results have been corroborated and widely accepted, but the pace of taxonomic discovery is so fast that classificatory change is still rather frequent. A real example is the almost complete restructuring of bacterial classification in the last 15 years (Figure 2.1-5).

The second common error found in taxonomic classifications occurs because primitive features of organisms have been mistakenly interpreted as novelties, or derived features, and used to define a group (see 2.1.3.1). In Figure 2.1-4, the cow, horse and cat are alike in characters 2 and 3. However, grouping these three taxa on the basis of characters 2 and 3 would be incorrect because they share no unique common ancestor. The only ancestor that includes cows, horses, and cats also includes foxes and wolves. The implication is that any biological prediction made for cows, horses and cats will either be true also for foxes and wolves (if it evolved at node 1, Figure 2.1-4), or for an even more inclusive group of mammals (if it evolved prior to node 1). Groups defined by primitive features are called paraphyletic because they include only some of the descendants' most recent common ancestors. For example, scientists used to call all animals except vertebrates the Invertebrata. But the only defining trait of invertebrates is the absence of a vertebral column, an absence equally well shared with tomatoes and, for that matter, stones. Aside from the original observation (that some species lack vertebrae), invertebrates as a group share no traits not also present in at least some vertebrates.

2.1.4 Characterizing species

For as long as humans have observed the tremendous diversity of life, they have attempted to sort organisms into recognizable kinds and to give names to them. In all groups of organisms the basic unit of classification is the *species*. The earlier concept of fixed and unchangeable kinds can be traced to the idealism of Plato and Aristotle. Belief in the notion of fixity continued to influence biology into the nineteenth century until destroyed by evolutionary thinking.

Today, species are recognized and conceptualized in three rather different ways. They may be seen to be distinct (the *morphological species concept*); members of the species may be united by shared inheritance from common ancestry (the *phylogenetic species concept*); and there may

be biological processes such as mating, recognition and behaviour that unite members of one species and distinguish them from others (the *biological species concept*). In many groups large numbers of species are easily recognizable, and, if investigated sufficiently, may satisfy all or several of these criteria. But in other groups and in other species, variation patterns may be obscure or insufficient information may be available: in some it may be difficult to find a workable species concept, in others a minority of species are in complexes where the boundaries are uncertain. It is, after all, an amazing achievement even to attempt to categorize into comparable units organisms as different as elephants and bacteria. Despite the universal and successful usage of the species, its precise definition is, and probably always will be, the subject of vigorous debate within the taxonomic discipline. There is no scientifically precise, universally applicable species definition. In practice there is no choice but to pursue a pluralist approach, using where appropriate one or other of the three main concepts given above.

A theoretical view is that each element in the classification is a hypothesis. This illustrates nicely the relation between the three main species concepts. The description of a species on the basis of the morphological concept is interpreted as hypotheses that (1) its unifying characteristics were inherited from common ancestors (the phylogenetic concept) and (2) there is in place some biological mechanism that maintains its distinctness from adjacent species (the biological concept). These hypotheses can then be tested.

The time when the species was considered the smallest unit of variation observed is long past. Detailed observation and knowledge of genetics mean that today biologists are extremely conscious of the range of variation that occurs within each species (see Chapter 2.2), and of the possibilities for classifying subunits within the species – subspecies, varieties and informal races in the wild; or cultivar groups, cultivars and breeds under domestication (see Table 2.1-1). However, the morphological and phylogenetic species concepts do still depend on being the smallest unit that is clearly distinct, or clearly diagnosable.

2.1.4.1 The morphological species concept

The most widely used method of recognizing species is referred to as the *morphological species concept*, defined in Box 2.1-4. The term morphological is, however, a misnomer as the concept is applied to any sort of comparative information on heritable characteristics (Davis and Heywood 1963) such as data on behaviour, phytochemistry and microanatomy. In the ideal case there is continuity of variation within and a distinct discontinuity between species. In practice it is the presence of clear discontinuities such as a correlated discontinuity in two or more characters that circumscribes the species (Hedberg 1958; Davis and Heywood 1963). Ideally all members will possess the diagnostic

characters of the species. In reality some species are polythetic, that is, defined by a combination of characters, any one of which might be absent in one member of the species, a property analogous to fuzzy sets in mathematics.

A variant of this concept is the *monotypic species*, widely used in the great Russian schools of taxonomy. Here emphasis has been on the smallest indivisible unit, that is, on uniform homogeneity within the units rather than clear discontinuity between them (Komarov 1944; Juzepczuk 1958). Such a system was considered by some authors to be advantageous in floristic work and in inventorying natural or genetic resources: every recognizably distinct form is named and catalogued separately.

A special case is used in the recognition of bacterial species where there are few morphological features. The DNA/DNA hybridization technique is used to assess the DNA resemblances of different bacterial strains. Strains with DNA resemblances above 70% are treated as members of the same species.

2.1.4.2 The biological species concept

In the nineteenth and early twentieth centuries attention turned to species as biological units, giving rise to what we now call the *biological species concept* (defined in Box 2.1-5). The concept emphasizes interconnected populations of interbreeding organisms. The key criterion for delimiting species boundaries is *reproductive isolation* (Vavilov 1931; Mayr 1963, 1970; Zavadsky 1968). The classical literature also refers to the *polytypic concept*, referring to something broadly equivalent to the biological species (Vavilov 1931;

Box 2.1-4: Morphological species concept.

Morphological species concept (Du Rietz 1930; Cain 1954; Mayr 1963; Shaw 1964)

The smallest natural populations permanently separated from each other by a distinct discontinuity in the series of biotypes.

Comment: The concept most commonly used by practising systematists. Many schools of application suggest a minimum of two correlated characters to characterize a sufficient discontinuity.

Criticism: Morphological or comparative criteria may not reflect actual links that hold organisms together into a natural unit. In sexually outbreeding organisms, some morphologically distinctive forms can freely interbreed to produce healthy, fertile offspring while other similar forms do not interbreed. Well known cases include cryptic species, polytypic species and ecophenotypes (Mayr 1963, 1982).

Box 2.1-5: Biological species concepts.**Biological species concept I** (Dobzhansky 1937; Mayr 1940, 1969)

A species is a group of interbreeding natural populations that are unable to successfully mate or reproduce with other such groups.

Comment: One of the most popular species concepts because it conforms to the popular view of how evolution occurs. An important point of this definition is that species are not distinguished by degree of difference, but by failure to reproduce with other species. Two species may appear extremely similar, but if they do not interbreed then they are two distinct species.

Criticisms:

- (a) It is irrelevant to asexual or parthenogenetic organisms where reproduction occurs without interbreeding even though their role in the ecosystem is the same as sexual species.
- (b) Relatedness and ability to reproduce are not always tightly linked (Rosen 1979; Baum 1992).
- (c) The amount of interbreeding between groups varies and it is not clear how much is necessary to identify two groups as belonging to the same species or how little indicates that the two are separate species. This question has been particularly troublesome in botany where phenomena such as natural hybridization, polyploidy, apomixis and interspecific introgression (see Chapter 2.2) complicate the delimitation of species (Levin 1979; Grant 1981).
- (d) Although the biological species concept may be accepted by biologists as an accurate description of what species are, it may not be used in practice by systematists because it can rarely be applied to real groups of organisms. Often reproductive isolation is inferred (not observed) from the absence of individuals with intermediate characteristics between two groups or by making assumptions about specific evolutionary processes (Mishler and Brandon 1987). Interbreeding is very difficult to observe in nature especially if groups are geographically or temporally separated. The systematist is effectively left having to guess whether groups would interbreed if they were living in the same time and place. Simply bringing the groups together in captivity or cultivation and seeing if they will cross is not sufficient as it is well known that under such artificial conditions many organisms will fail to breed even if they are members of the same species in the wild. Furthermore, separate species may breed in artificial conditions, even if they would not do so in the wild.

Biological species concept II (Mayr 1982)

A species is a group of interbreeding natural populations unable to successfully mate or reproduce with other such groups, and which occupies a specific niche in nature.

Comment: The introduction of 'niche' broadens the original biological species concept to include asexual and parthenogenetic species.

Criticisms: Criticisms b, c, and d of the biological species definition I (above) also apply to this concept. Furthermore, problems with defining 'niche' make this concept hard to apply in natural settings (Hengeveld 1988).

Recognition species concept (Paterson 1978, 1982, 1985; Vrba 1984)

A species is a group of organisms that recognize each other for the purpose of mating and fertilization.

Comment: This concept shifts attention from isolating mechanisms as barriers to breeding, to features that facilitate breeding among members of a species. It is supposed that the systematist is able to determine what features are important to the organisms in mate recognition. If this is possible, one could distinguish natural species in the same manner that the organisms do.

Criticism: Determining whether a feature is used to recognize potential mates is difficult or impossible to do in many wild populations. Furthermore, species that occasionally form hybrids would be considered the same species by this concept (Butlin 1987).

Cohesion species concept (Templeton 1989)

The smallest group of cohesive individuals that share intrinsic cohesion mechanisms.

Comment: Like the biological species concept and the recognition species concept, the cohesion concept accepts interbreeding ability as a mechanism that binds organisms into a group. In addition, it recognizes other mechanisms, such as niche requirement, as causing cohesion too.

Criticism: Cohesion is operationally difficult to recognize and applying this concept to problems of recognizing species in nature is almost impossible. Furthermore, it is not clear how to interpret varying degrees of cohesion between groups (Endler 1989).

Ecological species concept (Van Valen 1976)

A lineage which occupies an adaptive zone different in some way from that of any other lineage in its range and which evolves separately from all lineages outside its range.

Comment: The ecological species concept supposes that niches are discrete adaptive zones with gaps between. If an organism whose attributes adapt it for life in one of the gaps between niches will be maladapted: it will be fit to exploit resources that do not exist, or to avoid non-existent parasites or predators.

Criticism: Adaptive zones may be difficult to define in the real world, making this a difficult concept to apply practically. Furthermore, it is based on the often false premise that two species cannot occupy the same niche even for a short period of time (Wiley 1978).

Zavadsky 1968; Takhtajan 1984; Agaev 1987). In some cases a complex pattern of various forms is bounded by a discontinuity and the taxonomist infers, but without experimental work, that this is one polymorphic biological species.

The biological species concept has functioned well when applied to the major well-known groups of sexually outbreeding organisms. Indeed the link with population genetics and ecology had proved so robust that to many experimental and field biologists this has become the true species that exists as a biological unit, and whose membership can be determined by biological testing (see Chapters 2.2 and 2.3). What are often forgotten, however, are the real limitations on the applicability and functioning of the biological species concept (see Box 2.1-5). By its very definition it can only be applied to organisms with sexual breeding, and a large number of organisms do not fall in this category. Reproductive isolation also proves to be incomplete in some groups: it is particularly in plants that natural hybridization, introgression, the formation of polyploids from hybrids, and hybridization between polyploids (see also Chapter 2.2) all create circumstances where there is no clear demarcation (Stebbins 1950; Grant 1981). Manipulation of these mechanisms is of intense interest to plant breeders (see Chapter 2.2) and has lead to development of the gene-pool concept (Harlan and de Wet 1971), where Gene pool 1, (Figure 2.1-6), Gene pool 2, and Gene pool 3 represent various outer levels of hybridization and ocasional gene flow. But even this eminently practical scheme can be challenged on the basis that in nature there

are many examples of populations separated by only a few kilometres that rarely if ever exchange genes (Ehrlich and Raven 1969; Levin 1979).

2.1.4.3 *The phylogenetic species concept*

A second set of species concepts views species as the terminal twigs on the evolutionary tree. Speciation is the process by which new lineages originate. Similar

Figure 2.1-6: The gene-pool concept proposed by Harlam and de Wet (1971). Satisfactory only after all the taxa concerned have been intensively studied and satisfactorily classified.

Box 2.1-6: Evolutionary species concepts.

Evolutionary species concept (Simpson 1951, 1961; Wiley 1978)

A species is a single lineage of ancestor–descendant populations which is distinct from other such lineages and which has its own evolutionary tendencies and historical fate.

Comment: This broad definition is intended to define species in terms of the evolutionary process and would thus include living, extinct, sexual and asexual organisms.

Criticism: The concept is difficult to use when trying to identify species in nature because the criteria – evolutionary tendency and historical fate – are vague and difficult to observe (Hecht and Hoffman 1986).

Phylogenetic species concept (Rosen 1979; Eldredge and Cracraft 1980; Nelson and Platnick 1980; Cracraft 1983; Nixon and Wheeler 1990, 1992)

A species is the smallest group of organisms that is diagnosably distinct from other such clusters and within which there is a parental pattern of ancestry and descent.

Comment: This concept focuses on the phylogenetic history of organisms and considers a species to be the last diagnosable or undivided twig on a phylogenetic tree.

Criticism: As pointed out by Wheeler (1990), application of the phylogenetic species concept would almost certainly give far greater estimates of the total number of species than the more traditional biological species concept. As taxa are examined in more detail (especially with molecular genetic techniques), the chances of finding slight differences between small subgroups increases, and those would be named as separate species under this definition.

organisms, regardless of mode of breeding, owe elements of their resemblances to inheritance from a common ancestor. We thus have the *evolutionary species concept* (Simpson 1951) and the *phylogenetic species concept* (Cracraft 1983) (see Box 2.1-6). A difficulty, at least in long time-spans, is that an evolving species may eventually become so different that it can be considered a different species. At what point in time is the separation made (Lovtrup 1979)? In practice these concepts again recognize species on the basis of distinguishing characteristics: the results may not be much different from applying the morphological concept, in some cases, the emphasis is placed on the smallest phylogenetic element, so that, as with the monotypic concept, each recognizable unit may become a species.

A special form of the phylogenetic species concept has been adapted (ICTV 1991) for the definition of virus species. A virus species is a polythetic class of virus that constitutes a replicating lineage and occupies a particular ecological niche (Van Regenmortel 1990). The niche of a virus can often be quite clearly demarcated by environmental determinants such as host, tissue and vector tropisms (Franki *et al.* 1991).

2.1.4.4 The pluralistic approach

One can argue that for the whole of species diversity to be built on such an uncertain unit as the species is very unsatisfactory. It is, however, the best: the only unit that we have! Because many patterns of variation are found in

nature, a pluralistic approach to species demarcation is necessary to answer to the needs of taxonomists and other scientists working with different groups of organisms (Mishler and Donaghue 1982).

The vast majority of species are still recognized by taxonomists on the basis of observed discontinuity (the morphological species concept). Experimental investigation of breeding patterns and careful phylogenetic analysis enrich our knowledge and in many cases clarify species circumscriptions, but they are too expensive to apply to all species. In practice the classical process is cheap, effective and answers most needs.

One practical effect of the debate on species definitions is that the species concepts actually applied may be broader or narrower at different times or between taxonomists in different places. What are described and given the rank of separate species in one treatment may sometimes be aggregated into a single more inclusive species in another. Units given originally as separate species may then be described and named by another author as subspecies or varieties within one broader species. For example, several species of peas (wild species *Pisum elatius* and *Pisum humile*, and cultivated species *Pisum arvense* and *Pisum sativum*) were subsequently found to be interfertile and thus thought of as members of just one species (now *Pisum sativum*) using the biological species concept (Makasheva 1979). However, the originally discernable units are now referred to as botanical varieties within the one species (e.g.

Box 2.1-7: Different layouts for printed classifications. (a) is part of a Checklist giving a linear listing of taxa (Corbet & Hill 1991). (b) is part of a Flora showing the taxa again in linear sequence but now with descriptions and keys included in the sequence (Tutin *et al.* 1964–80).

(a) Checklist layout.

SUBORDER MICROCHIROPTERA

Family Rhinopomatidae

Greater mouse-tailed bat
(*Rhinopoma microphyllum*)

Mouse-tailed bats (rat-tailed bats, long-tailed bats); 3 species; Morocco, Senegal – Thailand, Sumatra; mainly desert and steppe; insectivorous.

Rhinopoma

<i>R. hardwickii</i>	Lesser mouse-tailed bat	Morocco, Mauretania, Nigeria – Kenya – Thailand
<i>R. microphyllum</i>	Greater mouse-tailed bat	Senegal – India; Sumatra
<i>R. muscatellum</i>		S Arabia – W Pakistan

Family Emballonuridae

Sheath-tailed bats (sac-winged bats, pouched bats, ghost bats); c. 49 species; tropics and subtropics of world; insectivorous.

Subfamily Emballonurinae

Sac-winged bat
(*Saccopteryx bilineata*)

Emballonura; Old-world sheath-tailed bats; Madagascar, S Burma – Pacific Islands.

<i>E. alecto</i> (<i>rivalis</i>)	Philippine sheath-tailed bat	Philippines, Borneo – S Moluccas, Tanimbar Is; ref. 4.143
<i>E. atrata</i>	Peters' sheath-tailed bat	Madagascar
<i>E. beccarii</i>	Beccari's sheath-tailed bat	New Guinea, etc.
<i>E. diana</i>	Rennell Island sheath-tailed bat	New Guinea, New Ireland, Malaita, Rennell Is, Solomons; ref. 4.26

(b) Flora or Fauna layout.

CLXVII. DIPSACACEAE¹

Annual to perennial herbs, rarely shrubs. Leaves opposite or verticillate, exstipulate. Florets in a dense, cymose capitulum subtended by involucre bracts, often with marginal flowers radiate, rarely in a spike of verticillasters. Florets hermaphrodite or female, usually zygomorphic, each with a basal epicalyx (involucre) of connate bracteoles which may be expanded distally into a *corona*, often subtended by a receptacular scale. Calyx small, cupuliform or divided into 4–5 teeth or of numerous teeth or setae. Corolla-lobes 4–5, subequal, or corolla 2-lipped. Stamens 2 or 4, epipetalous, alternating with corolla-lobes. Ovary inferior, 1-locular; ovule 1, pendent; stigma simple or 2-lobed. Fruit dry, indehiscent, enclosed in epicalyx and often surmounted by persistent calyx; seed 1, endospermic, with straight embryo.

- 1 Inflorescence a spike of verticillasters

1 Inflorescence of 1 or more capitula

2 Stems with prickles

2 Stems without prickles

3 Involucre bracts connate in basal half; calyx-setae present only in central florets of capitulum

3 Involucre bracts free; calyx-setae present or absent in all florets

4 Calyx-setae plumose

5 Fruiting involucre with longitudinal furrows running the whole length
1. *Morina*

3. *Dipsacus*

10. *Pycnocomon*

7. *Pterocephalus*

- 5 Fruiting involucre with 8 pits in distal half, furrowed below

4 Calyx-setae absent or, if present, not plumose

6 Calyx-setae or -teeth (6–)8–16(–24); receptacle hairy, without scales

6 Calyx-setae or -teeth 4–5 or absent; receptacle not hairy, with scales

7 Marginal florets radiate; corolla 5-lobed

7 Marginal and central florets subequal; corolla 4-lobed

8 Involucre bracts in more than 3 rows

8 Involucre bracts in 1–3 rows

9 Calyx-setae 4–5; involucre angled

9 Calyx-setae absent; involucre ± terete
9. *Tremastelma*

6. *Knautia*

8. *Scabiosa*

2. *Cephalaria*

4. *Succisa*

5. *Succisella*

1. *Morina* L.²

Perennial herbs. Leaves verticillate, spinose. Inflorescence a spike of many-flowered, bracteate verticillasters. Involucre long, infundibuliform, spiny. Calyx deeply 2-lobed. Corolla with curved tube, distinctly 2-lipped. Fertile stamens 2. Fruit with an oblique apex, rugose.

1. *M. persica* L., *Sp. Pl.* 28 (1753). Robust plant 30–90 cm. Leaves 15–20 × 1–2 cm, linear to elliptical, dentate to pinnatifid, glabrous. Verticillasters rather distant; bracts 2–4.5 × c. 1 cm, ovate-triangular, sometimes pinnatifid near base, with marginal spines up to c. 1 cm. Calyx-lobes subequal, entire or emarginate.

¹ Edit. D. M. Moore. ² By J. F. M. Cannon.

P. sativum var. *elatius*, etc.; Davis 1970). The reverse process can be seen with the application of phylogenetic species concepts to birds, where recognizably distinct subspecies under the biological species concept, usually geographical races, could be segregated into separate species using the phylogenetic concept. Regional inconsistency in assignment of the species rank by taxonomists can be seen in *Flora Europaea* (Tutin *et al.* 1964–80), where species described by Russian botanists using a monotypic concept have in a few instances been listed alongside wider species described by Western Europeans using the biological species concept. The broom genus *Chamaecytisus* is, for example, given as having a large number of narrow-concept species whose distribution stops abruptly at the boundary of the former Soviet bloc countries, and fewer broad-concept species west of this boundary.

For the vast majority of species the exact definition used makes little difference to the unit circumscribed. Only for the minority, usually where there are clusters of similar forms, can the concept used have the effects described. But users of the taxonomy should be aware that total species numbers may vary from one treatment to another, and in some groups the question of rarity and endemism may interrelate with varying views of what constitutes species.

This brings to an end our introduction to taxonomic and evolutionary characterization (2.1.0–2.1.4). What follows in Section 2.1.5 illustrates the wide and fundamental way in which the taxonomy underpins all knowledge of biodiversity: it provides a rich information structure and a picture of the natural map of diversity. Lastly, Section 2.1.6 highlights the view of many taxonomists and evolutionary biologists that the mere counting of species is a rather uninformative and unrepresentative way of measuring species diversity. The taxonomy provides a map, and species diversity should be characterized as dispersion on this map, with particular value given to distant islands and wide-ranging spans.

2.1.5 The power of taxonomy and taxonomic products

2.1.5.1 Taxonomic products: an essential technological infrastructure for biotechnology, natural resources management, and regulation

The single most important use of taxonomy is to provide the core reference system for organisms used throughout biology and its associated sciences and industries. The taxonomic classification is similarly the core reference system for biodiversity (Janzen 1993). This reference system is made available through the range of taxonomic products such as the Floras, handbooks and keys already discussed. The dissemination of certain basic information about the organisms is also traditionally incorporated with some of these, such as morphological descriptions and

images of flowers and leaves for plants, maps plus behavioural and song descriptions for birds, etc.

How are these products actually used to disseminate the reference system? Whilst there are many variations in detail, they are composed of just four principal features, each with its own function:

(1) **The classification.** The classification is given either as a concise checklist or by the structure provided by the sequence of organism entries in the book. (see Boxes 2.1-7 and 2.1-8). The classification provides reference information on the existence and taxonomic position of each organism.

Much the commonest starting point is the name of an organism. From the name one can learn what the organism looks like, where it occurs, what other organisms have similar characteristics or are genetically related to it, and much else about its biology and role in the environment: the name and the place in the classification provide a vehicle through which this information is obtained.

What if the enquirer does not know the name? In this case the enquirer must first go to the identification routine: find out the name of the organism under scrutiny. The quest for further information can then be the standard one starting from the name.

(2) **The nomenclature.** The nomenclature provides the scientific names used to label and retrieve organisms and groups of organisms. Users also need to be alerted to cases where an organism or group of organisms has previously been known by other names which can be treated as synonyms for the same. Because the names are needed to label the entries they are presented as part of the classification in products such as handbooks and Floras. Checking what the names are, and checking the spellings and authors are important infrastructure services for those dealing with organisms in many biological professions. Examples are given in Box 2.1-9.

(3) **Descriptions/circumscriptions.** To be logically complete, a taxonomy needs to provide not only a statement about what are the taxa, but also to circumscribe the range of variation among organisms found in each taxon. In practice, detailed circumscriptions are often kept for the technical taxonomic literature, but descriptions giving a word picture of the organism, or images of various sorts are often included as shown in Box 2.1-10. This important feature means that using many taxonomic products a user can find out what the organism listed looks like. So the enquiries illustrated in the boxes above (to find species related to *Vicia serratifolia*, or to check the name of Broom) can lead to a description, illustration and geographical distribution information for the species in question, as illustrated in Box 2.1-10.

(4) **Identification aids.** A variety of devices can be provided so that the user can examine an unknown specimen and determine where it belongs in the

Box 2.1-8: Examples of factual responses that can be obtained from the classification.

(1) Position

Where does taxon X fit in the classification? In which order, class or phylum is it to be found? Response, if X = Genus *Apis* (hive bees) –
in the order Hymenoptera (bees, ants and wasps)
in the class Insecta (insects)
in the phylum Arthropoda

(2) Members of a set

What other taxa resemble taxon Y? or What is the complete list of members of the taxon containing Y? Response, if Y = *Vicia serratifolia*
– one of 7 species in Section Faba of genus *Vicia*
– the 7 species are:
Vicia narbonensis
Vicia serratifolia
Vicia johannis
Vicia galilaea
Vicia kalakhensis
Vicia hyaeniscyamus
Vicia faba

(3) Subordinate taxa

What are the members of taxon Z? or Provide a systematic catalogue of all members of taxon Z? Response, if Z = Genus *Acetobacter*
Acetobacter aceti subsp. *aceti*
Acetobacter aceti subsp. *orleanensis*
Acetobacter diazotrophicus
Acetobacter hansenii
Acetobacter liquefaciens
Acetobacter pasteurianus subsp. *ascendens*
Acetobacter pasteurianus subsp. *estunensis*
Acetobacter pasteurianus subsp. *lovaniensis*
Acetobacter pasteurianus subsp. *paradoxus*
Acetobacter pasteurianus subsp. *pasteurianus*
Acetobacter peroxydans
Acetobacter xylinum

Box 2.1-9: Examples.

What is the correct (accepted) name for organisms labelled X?

e.g. if X = *Sarothamnus scoparius* (Broom)
response: *Cytisus scoparius*
(all species formerly known as *Sarothamnus* now usually included in *Cytisus*)

e.g. if X = *Vicia narbonensis* var. *serratifolia*
response: *Vicia serratifolia*
(now accepted as a separate species)

e.g. if X = *Cytisus scoparius*
response: *Cytisus scoparius*
(correct as given)

Under what names has taxon Y been known in the past?

e.g. if Y = *Rattus exulans* (Polynesian rat)
response: *Rattus exulans* (accepted name)
Rattus bocourti (synonym)
Rattus ephippium (synonym)

classification. The commonest device is the key (see Box 2.1-11) in which the user answers a series of questions about contrasted descriptive features, and by elimination arrives at the identification of what the organism is.

2.1.5.2 As a summary of biodiversity and evolutionary patterns

The taxonomy provides considerably more than the bare bones factual information system described above (the reference system): it also provides a summary of the pattern

of diversity and of the pattern of evolution in a group of organisms. The patterns are to be seen in the tree structure of the taxonomic hierarchy. Consider for instance the partial taxonomic hierarchy of gymnosperms shown in Figure 2.1-7.

The hierarchy depicted shows the reader that *Ginkgo biloba* (the maidenhair tree) is the only living representative of the order Ginkgoales, and that it is thus very isolated and distinct in terms of diversity from the nearest other group, the Coniferales (Conifers). Conversely, the Coniferales is made up of seven families, each of which contains several genera and many species, amounting to a total of 610 species (Mabberley 1987). For instance, the Pinaceae (Pine family) contains 10 genera, of which *Pinus* contains about 120 species world-wide and *Abies* 55 (Rushforth 1987). *Pinus* and *Abies* species are thus nowhere near being so isolated as *Ginkgo biloba*: each species has a number of other species so close or similar as to be in the same genus, and a number of close or similar genera exist within the same family and in six related families. This then is the description of a pattern of species diversity. This diversity pattern allows us to quantify the diversity of, say, forests composed of just two species of gymnosperm: the forest whose two species are both pines (*Pinus* spp.) has low diversity (they are both in the same genus), the forest with one *Pinus* and one *Abies* comes next (its species are in related genera of the same family), whilst

Box 2.1-10: Examples of descriptions, illustrations and maps from Greenwood 1987 (a), and Valdes et al. 1987 (b). The description in a) is part of a “diagnosis” or “circumscription”, an exact complete technical description of the animal. The description in b) is a brief synoptic description that could be used by botanists in general.

(a) Part of a ‘diagnosis’ and illustrations from Greenwood 1987.

Scale bar in mms.

(b) A description, map and illustration from Valdes et al. 1987.

Muy raro. Rupícola. Algeciras.
Distribución general. Regiones
Eurosiberiana y Mediterránea.

3. **Polypodium interjectum** Shivas, *Journ. Linn. Soc. London (Bot.)* 58: 29 (1961)
P. vulgare subsp. *prionodes* (Ascherson) Rothm., *Mitt. Thüring. Bot. Vereins* 38: 106 (1929)
P. vulgare auct., non L., *Sp. Pl.* 1085 (1753)

Rizoma más o menos largo con escamas densas. Escamas de (2-) 3-6 (-8) mm, linear-lanceoladas. Hojas de (14-) 17-22 (-30) cm; limbo generalmente más largo que el pecíolo, con la anchura máxima hacia la mitad, de ovado a ovado-lanceolado, gradualmente acuminado. Pinnas agudas. Soros elípticos, sin parafisos, a veces con pelos glandulares. Anillo del esporangio con (4-) 7 (-13) células engrosadas y 2-3 células en la base. 2n = 222. *Esporula de Julio a Septiembre.*

Box 2.1-11: Two examples of printed indentification keys. (a) ‘indented’ type – the first two contrasting leads are labelled ‘1’; if the lower of these is selected, the next pair labelled ‘2’ are indented, and so on. (b) The ‘bracketed’ type, where the contrasting leads are printed (or sometimes bracketed) one below the other, J2 and its partner, J3 and its partner, etc.

(a) Indented key to genera Turkish Gymnospermae (Davis 1970).

SPERMATOPHYTA

GYMNOSPERMAE

Krause, K. 1936. *Türkiyenin Gymnospermleri*. Ankara. Kayacik, H. 1959. *Orman ve Park Ağaçlarının Özel Sistematigi*. 1. Cilt: *Gymnospermae* (Acik Tohumlar). Istanbul.

Key to Genera

1. Leaves reduced to scales at the nodes; equisetoid shrubs (*Ephedraceae*)
Ephedra

1. Leaves not reduced to scales at the nodes; trees or shrubs, not equisetoid

2. Mature leaves scale-like, imbricate and adpressed, or linear-lanceolate and articulate at the base (*Cupressaceae*)

3. All leaves scale-like and imbricate; fruit a woody cone; seeds winged
Cupressus

3. At least the juvenile leaves linear-lanceolate, not scale-like and imbricate; fruit fleshy, berry-like; seeds unwinged
Juniperus

2. Mature leaves oblong-linear, not articulate at the base

4. Leaves without resin canals; fruit surrounded by a fleshy aril (*Taxaceae*)
Taxus

4. Leaves with resin canals; fruit a woody cone, exarillate (*Pinaceae*)

5. Mature leaves borne on short shoots, in whorls or fascicles of two

6. Leaves in fascicles of two, each fascicle surrounded by a sheath at the base
Pinus

6. Leaves in whorls, without sheaths at the base
Cedrus

5. Mature leaves borne spirally on long shoots; short shoots absent

7. Branchlets with numerous peg-like projections persisting after leaf-fall; cones pendulous, falling as a whole
Picea

7. Branchlets without such projections; cones erect, the scales falling from the persistent axis
Abies

(b) Bracketed key to beetle families of Britain (Unwin 1984).

Beetles with elytra covering most of the abdomen. Antennae clubbed, and tarsi with some segments lobed beneath.

J1 Number of tarsal segments:
Note: in this key, small cylindrical tarsal segments (arrowed) immediately following a bilobed segment are ignored. Claws do not count as segments.
Tarsal characters may be easier to see if a drop of water is placed on the tarsus.
Tarsi with 5 segments J2
Tarsi with 4 segments J5
Tarsi with 3 segments J19

J2 Thorax constricted basally, beetles with a very obvious “waist”. Thorax with out-standing long hairs CLERIDAE

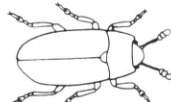

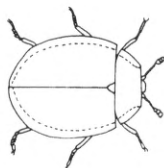

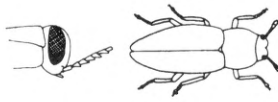

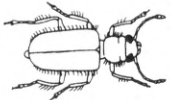

— Beetles without a distinct “waist” between thorax and elytra J3

J3 Eyes oval, over twice as high as wide, occupying most of the height of the head BUPRESTIDAE

— Eyes approximately circular J4

J4 Oval beetles with a wide turned-out rim to the elytra and the thorax giving a terrapin-like appearance. Tibiae not flattened and expanded PELTIDAE

— Beetles with at most a narrow “beading” on thorax and elytra. Tibiae flattened and expanded EROTYLIDAE

the forest (if such were to exist) with one *Pinus* and *Ginkgo biloba* has a relatively enormous diversity, because its two species are in separate orders. This patterned or qualitative view of diversity provides the basis for taxonomic or taxic measures of diversity discussed in the next section.

The same classification hierarchy can be taken to imply the shape of the evolutionary tree or phylogeny. For instance, two elements of the evolutionary pattern might be:

1. that *Ginkgo* separated from the evolutionary line of conifers at an early date, and

2. that members of the Coniferales are thought to be monophyletic, that is with a common ancestor more recent than the one they share with *Ginkgo* and with all the descendants of that common ancestor included in the Coniferales group.

However, as noted earlier, the taxonomic hierarchy can at best only loosely mirror the branching pattern of the cladistic tree. A more precise view of the hypothesized route of evolution will be obtained by examining in addition any published phylogenies for the group.

2.1.5.3 As a basis for prediction

The natural pattern reflected in the taxonomy enables scientists to make predictions about as yet unobserved features of organisms. These predictions are only probabilistic, but they can provide a powerful and economically important basis for directing future biological research. One example is the successful search for castanospermine-like substances of possible significance in HIV research in South American legume plants of the genus *Alexa*. The substances were first discovered in an Australian plant cultivated in South Africa. This was *Castanospermum australe* (Moreton Bay chestnut), the only species at that time in the genus. When phytochemists wanted to look for the substances in other plants, taxonomists predicted that the highest chance of finding similar properties would be in geographically distant *Alexa*, a South American group but, taxonomically, the closest genus to *Castanospermum*. The prediction was correct and substances related to castanospermine were successfully isolated from the South American plants. In contrast, the chances of locating the substances rapidly by a random (and consequently expensive) search amongst the 280 000 or so Flowering Plants, or indeed amongst the 1.75 million known

to a postulated African female, ancestral to all modern humans. Another use is to reconstruct the evolution of complex molecules where different variants of the molecule are present in the same organism: a classic example is the evolution of globin and haemoglobin molecules (Jeffreys 1982).

2.1.6 Taxonomic measures of species diversity

A matter for substantial debate is the question of whether all species, or indeed all higher taxa (families, genera, etc.), are to be valued equally. As described in Chapter 2.3, the most widely used measure of within-area diversity is species richness, a simple count of the number of species present, or the diversity of an ecosystem. All species are thus counted as equal. In contrast, there is a view that individual species vary enormously in the contribution they make to diversity because of their taxonomic position, and that as a consequence measures of ecosystem diversity should include a taxonomic measure of diversity amongst the species contained. Two particular arguments are the widely expressed view (IUCN 1980) that taxonomically isolated species or species of isolated genera are of high value (such as the ginkgo, *Ginkgo biloba*, the tuatara, *Sphenodon*, or the coelacanth, *Latimeria chalumnae*) and that when valuing sets of species, a wide taxonomic range of species encompasses more species diversity than an equal number of closely related species from the same genus. Faith (1992) introduced the concept of *feature diversity* and links this to the discussion on option value and conserving variation for future use (McNeely *et al.* 1990).

Although most taxonomists and evolutionary biologists have clear concepts of taxonomic isolation and of taxonomic diversity, there were until recently no precise measures by which these concepts could be quantified. Initial suggestions by May (1990), Faith and Cawsey (1990) and Vane-Wright *et al.* (1991) led to proposals for a quantitative framework which is further developed, along with examples of application to conservation evaluation, in the symposium volume *Systematics and Conservation Evaluation* (Forey *et al.* 1994).

2.1.6.1 Evaluating taxonomic isolation of individual species

The traditional method of referring to isolated species has been to label a taxon in the classification as *monotypic*: a *monotypic genus*, *monotypic tribe*, *monotypic family* or *monotypic order* contains just one species. A quantitative scale, analogous to what is called node counting (Faith 1994) is implied in this measure. For instance, use of the phrase *monotypic genus* implies that the one species is isolated at one level of the taxonomy, but maybe not at the next level, where this and other genera may belong to the same tribe. *Monotypic family* (one species in a family) means that the tribe and genus levels must also be monotypic, so this family

is monotypic at all three levels. Examples include *Ginkgo biloba*, sole species in the Ginkgoaceae discussed above, the fern *Loxoma cunninghamii* (New Zealand), sole species in the genus *Loxoma*, and many others. The node-counting analogy, however, is obscured by the fact that taxonomists do not bother to name monotypic taxa at many ranks for a single species as it would serve no purpose, whereas in species-rich groups they use many intermediate ranks (subfamily, tribe, subtribe, subgenus, section, subsection). Whether or not a group is monotypic must be seen in relation to a time frame. The Ginkgoaceae, for instance, is monotypic today, but other now extinct species occurred earlier in the fossil record.

The monotypic measure is a measure of isolation from the isolated species to the nearest other species in the classification, or if the tree is derived from a phylogeny, from the closest related species. Several authors (Faith and Cawsey 1990; Crozier 1992; Faith 1992; Weitzman 1992) have proposed quantitative measures of species distinctiveness. The method of Faith (1992) measures spanning sub-tree length (distance along branches of the phylogenetic tree) between an isolated species and its closest related species, ideally measured on a fully worked phylogeny. Where a phylogenetic tree is not available Faith suggests using the distances along branches of the classification tree, effectively node counting as with traditional monotypic statements.

These measures may be used in conservation evaluation where a set of species is already protected (e.g. by law, within other reserves, in other countries), to evaluate which is the most isolated species whose additional protection would add most to the set already conserved. Faith (1992)

Figure 2.1-8: A map of Australia showing botanic regions. Numbered regions are those making high contributions to phylogenetic diversity (from Faith 1994).

Figure 2.1-9: Classification of eight surviving species showing which biotas of just three species would score most highly when using each of the measures of taxonomic diversity. The selected species are shown by black spots, with any equally highly scoring alternatives for each choice shown bracketed by dotted lines. The groups within the classification that are essential to represent high diversity value using each measure are shown in black, groups which remain alternative choices are shown stippled, and groups which are of low diversity value are shown in white outlined in black (from Williams & Humphries 1994).

describes using his measure to evaluate orchid floras in Australia. Thirty-two species and two endemic genera, *Trichoglottis* and *Aphyllorchis*, occur in the Cape York region (Region 40 in Fig. 2.1-8). He applies his measure (to the albeit poorly known phylogeny of orchids) to evaluate which of the 71 regions contains other orchid species whose degree of taxonomic isolation would add most if added to the protected set. Region 63 (Central Coast, New South Wales) and Region 1 (SW Western Australia) add

most, followed by Regions 53, 66, 67 and 71. The result is interesting both because of the evident complementarity implied (Regions 40, 63 and 1 are at diametrically opposite corners of Australia with widely different habitats), and because the ranking of evaluations was different from that obtained by valuing numbers of endemic species, the species traditionally thought of as valuable or at risk. Complementarity means that effective conservation of a valuable subset of taxa requires attention to conserving

Figure 2.1-10: (a) Systematic position of *Sphenodon* (see Daugherty *et al.* 1990). Inset indicates geographical distribution of *Sphenodon*, restricted to the islands of New Zealand. (b) Systematic position of *Latimeria* (see Rosen *et al.* 1981). Inset indicates the geographical distribution of *Latimeria*, restricted to deep water habitats off the islands of Grande Comore and Anjouan.

taxonomically different, complementary taxa often in different habitats, rather than focusing on single species hot-spots or areas of endemism.

2.1.6.2 *Measuring taxonomic diversity of biota or ecosystems*

Williams and Humphries (1994) review the methods proposed for measuring the taxonomic spread or diversity covered by a set of species, such as those in a single ecosystem or biota. They too assume that the methods will be most widely applied to the taxonomic hierarchy itself, although in some cases a phylogeny may be available. The differences between the measures are illustrated in Figure 2.1-9, taken from their paper, which illustrates how different measures would lead to the selection of different species for conservation in an example set.

It has been suggested that a key element in taxonomic diversity is the number of higher taxa present, or to focus on the *basal taxa* in a phylogeny or cladistic tree (Williams *et al.* 1991; Stiassny 1992). Stiassny and de Pinna (1994) have reported an intriguing number of cases of high-level phylogenetic asymmetry where the basal taxa on a tree are both monotypic or bi-typic relict species, *and* endemic, *and* rare, such as *Sphenodon* and *Latimeria* illustrated in Figure 2.1-10. Endemism and rarity are eco-geographic features, however, largely unrelated to taxonomic isolatedness. Two of the measures that take into account higher taxa, the root weighted method of evaluation (Vane-Wright *et al.* 1991) and the higher taxon richness method (Williams *et al.* 1991), are illustrated in the comparisons in Figure 2.1-10.

Versions of a direct measure of taxonomic spread have been proposed by Faith (1992), as the node-counting version of phylogenetic diversity, and by Williams *et al.* (1993) as cladistic path length. Both can be referred to as *spanning-subtree length* measures. The number of nodes on the taxonomic tree needed to link the taxa is counted, each node being counted only once.

Finally, Williams and Humphries (1994) have attempted to refine spanning sub-tree length with their *cladistic dispersion* measure which values an even representation, or evenly dispersed taxa where alternative biotas would otherwise tie on spanning sub-tree length. The method is again visualized in Figure 2.1-9.

2.1.7 *Conclusion*

1. Taxonomy provides the core reference system and knowledge base on which all discussion of biodiversity hinges, providing the framework within which biodiversity characterization occurs. Taxonomic characterization for all known organisms is a mammoth but essential infrastructure task with which only limited progress is being made: just 1.75 of the estimated 13 million species have so far been described, and most of

these are still poorly known in biological terms. There is not even a comprehensive catalogue of these 1.75 million known species.

2. Systematic and evolutionary studies are now providing valuable knowledge about the phylogeny of life, the scientific map of diversity. This is the map on which conservation, prospecting, exploitation, regulation and sustainable use must be planned and, indeed, without which all might be lost. It is important that assessments used in the evaluation of resources and conservation options make adequate use of taxonomic diversity measures that do take into account the positions and differing contributions made by different species.

2.2 Genetic diversity as a component of biodiversity

2.2.0 Introduction

In this Chapter we outline various aspects of biological diversity within the species. This diversity is variously termed subspecific (meaning below the species level), intraspecific or infraspecific (both meaning within the species, but the former term apparently more favoured by zoologists and the latter by botanists). A major aspect of this is obviously what is termed genetic diversity (see below), but it should be borne in mind that within biology, genetics and systematics are, or at least should be, intimately linked and that there are a considerable number of groupings below the species level which have taxonomic or systematic implications without necessarily being clearly defined in genetic terms. A number of the subspecific groupings more commonly referred to are outlined in Box 2.2-1. Some of these (e.g. subspecies, varieties) are or have been used as straightforward subspecific taxa. Others (e.g. ecotypes, chemotypes) imply differences based upon other than conventional systematic characters or (e.g. cytotypes, hybrids) have mainly genetic implications. The explanations suggested for these terms are not intended to be strict definitions and for many of them the intended meaning differs, often subtly, between authors and between fields of research and some, like the organisms they describe, have evolved with time and may no longer be used in precisely the same sense as they were by earlier workers. However, irrespective of meaning and usage, such intraspecific groupings generally can be assumed to imply some, albeit imprecise, level of genetic differentiation or genetic biodiversity.

Genetic diversity is a critical component to issues of biodiversity. It is the genetic diversity within species that allows a species the opportunity to evolve under changing environments and selection pressures. This section will overview the main fields of evolutionary genetics as applied to the assessment of biodiversity and introduce briefly various techniques available to assay genetic diversity within and between species.

Figure 2.2-1: Examples of some phenotypic variants found in natural *Drosophila melanogaster* populations: sketches of normal flies are presented for comparison. A relatively small proportion of such abnormal flies owe their abnormality to single mutant genes (from Hartl and Clark 1989).

The variability that we observe among individuals (*phenotype*) results partly from the interaction of genetic differences (*genotype*) with their surrounding environments. Genetic diversity both within species and among higher taxonomic groups can be assayed directly by surveying the actual genetic material (i.e. the genotype). The genetic diversity occurs in the form of nucleotide variation within the genome. When this variation causes a change in a given protein, the variants are termed *alleles*. Allelic variation occurs at various genetic *loci*, or gene positions within a chromosome. Genetically variable loci are termed *polymorphic* or are said to show *polymorphism*. Genetic diversity can also be assayed indirectly by measuring a phenotype with a presumed or demonstrated underlying genetic basis (Figure 2.2-1). As one moves up the taxonomic hierarchy, genetic diversity tends to increase with increasing taxonomic diversity, both within organismal groups (Figure 2.2-2a) and across groups as a whole (Figure 2.2-2b).

The recognition that natural populations have high levels of genetic variation is something comparatively recent and followed from the application of allozyme electrophoresis to population genetics (Hubby and Lewontin 1966). This resulted in debate as to the factors responsible for the maintenance of these high levels of variation: the 'neutralists' claimed that genetic variation accumulated through mutation to form new alleles, which remained in

Box 2.2-1: Definition of terms.**Clines**

These are examples of regional variation in one or more characters which vary unidirectionally over a significant geographical distance. One of the problems with detecting clines (and even with the concept) is that their detection and characterizing is through sampling a range of populations which may make it difficult to know if variation is gradual or punctuated. It is assumed that clines are responses to gradual regional changes in such factors as climate (e.g. high to low rainfall), altitude and distance (e.g. decreasing maritime influence), but suggested that clines do not always match obvious changes in habitat parameters. Examples include regional changes in morphology of North American trees such as Douglas fir and spruce species, Australian eucalyptus, and *Celmisia spectabilis* along the Southern Alps of New Zealand (Given 1994).

Ecotypes

In those instances where there are morphologically distinctive forms of taxa restricted to identifiably different habitats the term 'ecotype' is used. Ecotypes may therefore overlap geographically, and often will, but are frequently identified in terms of restriction to particular soils, or climatic regimes (e.g. low versus high rainfall ecotypes). Examples of ecotypes include glaucous and non-glaucous forms of *Phyllocladus aspleniifolius* in New Zealand where this has partial correlation with altitude and with soil type.

Chemotypes / pathotypes

Similar to the above but identified in terms of chemical characteristics, physiological characteristics and pathological distinctiveness, which may not necessarily have an obvious morphological or genetic correlation. These may be widespread, but obviously are more difficult to detect because they are examples of 'cryptic taxa' (i.e. they are not morphologically obvious). They have been detected in several New Zealand plant groups, e.g. South Island *Chionochloa*, some Hymenophyllaceae.

Cytotypes

This term is used for forms of an organism which may not be readily distinguished morphologically, but which have clear differences in, for example, the number or conformation of chromosomes. Examples occur particularly in the fern genera *Asplenium* and *Dryopteris*. They are also known in the whelk genera *Thais* and *Nucella* in North America and Europe respectively.

Varieties and subspecies

Species often consist of two or more forms which can be distinguished on the basis of, for example, morphology or colour. If considered sufficiently different to require some taxonomic distinction, but not to be separate species, such forms may be given the status of subspecies. An example is the migratory passerine bird *Motacilla alba* (white wagtail), which breeds over much of the Palaearctic, but with such plumage variation in different areas that several subspecies are recognized (see Cramp *et al.* 1988). Varieties were often used in older taxonomic work to give names to colour morphs or other distinguishable forms within a species. For example, Gosse (1860) gave varietal names to many colour morphs of the intertidal sea anemone *Actinia equina* occurring around Britain.

Polytypic and monotypic taxa

Many (perhaps most) species consist of a single scientifically recognized entity, termed monotypic. Others may consist of two or more entities (subspecies, varieties) and are polytypic. Most species are related to other species which collectively form genera: these in turn are aggregated into families, and so on upwards through the taxonomic hierarchy as described in Chapter 2.1.

Hybrids

When species hybridize, some of the offspring may be fertile (forming a hybrid swarm), and true-breeding forms may become genetically stable. These can disperse and establish new colonies. The remainder of the swarm may often become extinct because of lack of fitness. If habitats are sharply distinct and there is only a small intermediate zone between them, hybrids of species from each habitat may be unable to survive. However, where there is a wide transition from one to another, fertile hybrids, (or offspring capable of vegetative reproduction) may be able to exploit

the intermediate site, or 'ecotone'. This has occurred with *Ceanothus* in parts of central California (*C. cuneatus* and *C. gloriosus*), *Platanus* – the sycamore or plane trees – (*P. orientalis* of Eurasia and *P. occidentalis* of North America giving *P. × hybrida*: the London Plane) and *Celmisia* in New Zealand (*Celmisia spectabilis* and *C. lyallii* giving *C. × pseudolyallii*). Hybridism is widespread in some particular plant groups and regions (e.g. New Zealand where hybridism is rampant, especially where habitat change has created 'intermediate' habitats). Many hybrids are sterile but there are others which are at least partially sexually reproducing and form hybrid swarms. When this occurs there may be a gradation from one parent to the other, through a series of intermediate plants. Hybridism has a significant role to play in evolution of new taxa. This is especially the case where the hybrids have different chromosome numbers from the parent species (amphidybrids: hybrid plus polyploidy), and so the offspring are reproductively isolated. Hybridity has mixed results for biodiversity. Positive input is one means of enhancing genetic diversity – an obvious one, for it allows the mixing of different genotypes. Offspring from such unions are often more vigorous than either parent. This is the phenomenon of 'heterosis' or hybrid vigour. The explanation is that most individuals carry genes which are disadvantageous. Unrelated individuals are less likely to carry the same such genes than are close relatives. Therefore in hybrids, the progeny are more likely to have disadvantageous genes masked by 'normal' dominant ones. Heterosis is important to conservation biology because of its relationship to fitness (see Ledig 1986). However, other hybrids, even between closely related species are inferior to either parent. In fact, interspecies hybridism is often associated with breakdown of finely tuned gene complexes and with developmental instability. Corn (*Zea mays*) is the classic example of heterosis but even here there is an optimum amount of parental divergence for maximum hybrid vigour. With greater parental difference decline in fitness sets in: this is referred to as 'outbreeding depression' or 'coadaptation'.

The marine grass, *Spartina × townsendii*, was first formally recognized and described in 1881 from specimens collected near Hythe, Southampton Water, England, although it had been collected as early as 1870 or possibly earlier. It is generally believed on morphological and cytological grounds to have resulted from hybridization between the indigenous *S. maritima* and introduced *S. alterniflora*. Original plants were male-sterile, but hybridisation was followed by doubling of chromosome number to produce fertile, vigorous offspring which behaves as a 'good' species. This has been described as *Spartina anglica*.

Negative implications of hybridization

Hybridization between a widespread species and a narrow endemic can end up eliminating much of the genetic diversity present in the narrow endemic. This is the case of *Centaurea avilae* Pau, a narrow endemic of Central Spain, which grows in Sierra de Gredos at 1800–2000 m altitude. The habitat of the species is frequently visited by mountaineers, who use it as a camp-site. This has led to the nitrification of part of the habitat and its colonization by the more widespread *C. alba* L. The two species are hybridizing and the original genotype arrangements of *C. avilae* are being lost (Blanca *et al.* 1987). Another example is *Acaena pallida*, a local sand-dune endemic of New Zealand, which is being hybridized with *A. novae-zelandiae* naturalized from Australia.

For 100 years the distributions of British *Gentianella* have decreased in numbers of individuals and sites. Only one species, *G. amarella*, seems not to be seriously diminishing, although it has been adversely affected by people and the loss of rabbits. Several species may be the victims of environmental changes which have caused breakdowns in breeding barriers. These species have geographic ranges within that of more widespread *G. amarella*. They are not genetically isolated from the more widespread species. As habitat changes allow *G. amarella* to invade the ranges of the other species, introgressive hybridization occurs. Hybrid populations are weighted morphologically towards *G. amarella*, so that there is gradual 'absorption' of the rarer species into the more abundant one. Examination of herbarium specimens and field data supports this hypothesis for the gradual extirpation of several rare species and it is assumed that (at least in their 'pure' form) these will disappear.

Conservation of *Agave arizonica*, a recurring hybrid

Soon after its discovery in 1959, *Agave arizonica*, one of the rarest and most attractive agaves in Arizona, was known from about ten sites over an area of about 50 km² in the New River Mountains. By March 1984 ten new sites were known from the region, but only one of the original clones had persisted. All sites are within the distribution area of two other species of *Agave* – *A. toumeyana* subsp. *bella* and *A. chrysantha*. Comparison showed that *A. arizonica* is intermediate between the other two species, and it has been concluded that it is a recurring hybrid between them. Many

Box 2.2-1 cont.

species of *Agave* have arisen by hybridization, this group of plants adopting polyploidy, hybridization and vegetative reproduction as evolutionary strategies. However, because of the hybrid nature of *Agave arizonica*, attempts have been made to remove it from lists of endangered species – specific reasons have been its low reproductive potential, the inability to maintain itself in discrete populations in nature, and its uselessness as an easily created plant through artificial propagation. This raises the question of the best means of dealing with species that appear to be of recent hybrid origin in this and other genera. *Agave arizonica* may be an early stage in the evolution of a new species, before reproductive patterns have become fixed (DeLamater and Hodgson 1987).

Aggregate species

Aggregate species are species that are generally characterized by being very widely distributed, often with a wide variety of habitats, and with a large degree of (usually) morphological variation, which can be correlated with geographic and/or habitat variation. The infraspecific components (microspecies) are difficult to recognize as species in their own right, yet may behave as independent species locally. In some instances they may form ‘circle species’ in which microspecies are replaced sequentially, in circular fashion over a whole continent (or large geographic area): $a > b > c > \text{etc.} \dots n > a$. Investigation of many aggregate species shows that they are at least in part apomictic in their breeding system. There is a tendency for new microspecies to arise spontaneously in answer to changed environmental parameters. Examples of classic aggregate species include the genera *Rubus* (especially the European ‘blackberry’ species), *Hieracium* and *Rosa*.

Polyploid complexes

Polyploids are especially widespread among plants – situations where there is increase in the number of chromosome complements (or sets) above the usual diploid level. Although often said to be disadvantageous, and even an evolutionary dead-end, polyploidy has been widespread and probably highly significant in the evolution of most plant groups. Polyploidy is regarded as one of the fastest ways of speciation in plants because genetic barriers between the individuals that undergo polyploidy and the original population are formed in just one generation. It is estimated that one-third of the angiosperm species have more than two chromosome complements (are polyploids). For example, in the fern family, Hymenophyllaceae, there are a range of base chromosome numbers and most species are parts of polyploid sequences based on these, modified by aneuploidy or reduction in number as well. Within some species of *Hymenophyllum* there are polyploid sequences within species.

Polyploidy is more frequent in some particular families and regions. New Zealand has a particularly high level of polyploidy, especially in Poaceae and Asteraceae. In the latter, the genus *Celmisia*, which is in the same general group of genera as *Erigeron* and *Aster*, the lowest ploidy level recorded is $n = 12$, and there are species that are $n = 24$, $n = 36$. The related genus *Olearia* has ploidy levels ranging from probable diploids and tetraploids to at least $n = 24$, with series based on $n = 4$, $n = 6$, $n = 10$.

Polyploidy not only occurs between species but can occur within species. An example is *Asplenium trichomanes*. This species which has world-wide distribution, has at least three karyotypes (diploid, tetraploid and octoploid) which have been recognized in formal taxonomy of the species. Another example is *Narcissus bulbocodium* L. where diploid ($2n = 14$), triploid ($2n = 21$), tetraploid ($2n = 28$), pentaploid ($2n = 35$) and hexaploid ($2n = 42$) karyotypes are known. Polyploidy is a lot less frequent in animals than in plants and it has played a less important role in its evolution. Polyploidy is rare among animal species, generally because in most groups polyploids seem to be either non-viable or sterile. They appear to be relatively common in sea anemones (e.g. Shaw *et al.* 1987).

the population because they were selectively equivalent to the original ones (i.e. selectively neutral; Kimura, 1983, 1991), whilst the ‘selectionists’ interpreted the high levels of gene variation as adaptation to a number of different environmental parameters (reviewed by e.g. Lewontin 1974; Nevo *et al.* 1984). However, it became well established that, whatever the reason, most natural populations had high genetic diversity. All current methods

used relate to the estimation and comparison of genetic diversity in different organisms.

Genetic diversity originates by mutation, but different processes determine the extent to which it is maintained within populations. The relative importance of these processes varies substantially among different organisms as a consequence of their ecology and life histories. *Natural selection* operates via the differential survival and

Figure 2.2-2: (a) Percentage sequence divergence for the 16S region of the mitochondrial DNA obtained from nested taxonomic groups of freshwater crayfish (Decapoda: Cambaridae, Parastacidae). Average percentage sequence divergence is shown between two of the stated taxonomic groups. e.g. 1.8% sequence divergence between populations of a single species. Sequence divergences are calculated from data given in Crandall and Fitzpatrick (1994). (b) Allozyme divergences. Probability against Nei’s Genetic Identity for genera, species and populations. (Redrawn from Thorpe 1982.)

reproductive success of individual organisms. Those individuals with well adapted phenotypes will pass on a greater proportion of their genes to the next generation. As a consequence, gene frequencies in the population change allowing individuals to adapt to changing environments. Therefore the capacity for populations to persist under changing environmental conditions is at least partly determined by the amount of genetic variability. A second process that alters gene frequencies is *genetic drift*. Random assortment of genes at each generation means that some may increase in frequency, some may decrease and some may be lost. The importance of genetic drift as a source of genetic variation is inversely related to population size. The manner in which genetic drift may affect genetic variation in populations was shown empirically by Bonnell and Selander (1974) in an early study of genetic variability at enzyme loci in the elephant seal *Mirounga angustirostris*. Hunters had reduced the total population of this species to only several individuals before legal protection was granted earlier this century. Although the population is now much larger, genetic variability has been almost eliminated, presumably through the predictable effects of genetic drift on the previously very small population size. Gene frequencies may also be altered through *migration* if migrants entering the population have different genotypes and interbreed with residents. The importance of migration in altering gene frequencies increases if the number of effective migrants is large and if

gene frequencies differ substantially between the migrants and residents. Analytical techniques for detecting the influence of these various processes are described in Chapter 2.2.3 (Box 2.2-4). The processes generating and maintaining genetic variation within and among populations are expounded upon in Chapter 3.2.

2.2.1 Partitioning of genetic variability below the species level

Given the huge number of gene loci (of the order 10^5) in higher organisms, and the number of alleles at each locus, in sexually reproducing species the reshuffling of the genetic material during meiosis results in each individual having a unique combination of alleles. Consequently estimates of gene composition can discriminate between different individuals providing that the analysis is undertaken using a genetic system of sufficiently high resolution (see below). Patterns of genetic variation above the level of the individual reflect patterns of species substructuring, and the extent to which there is gene flow between the different units. For example, within breeding groups there will be a greater genetic similarity than among such groups. The level of difference between populations of a species will depend, in part, on the amount of genetic interchange (gene flow) between them.

By definition, different biological species are not expected to exchange genes and, therefore, they will start to accumulate differences (i.e. they will undergo *anagenic*

Box 2.2-2: Genetic adaptation in butterflies.

Examples of how a single species may adapt by using different genes to fit it to the varied ecological requirements of different habitats and areas are provided by tropical butterflies. In Africa, various species of *Papilio* are widespread and each is colourful, but highly variable. The species are palatable to birds, but survive partly by looking like other butterfly species that are poisonous (i.e. they are what are termed *Batesian mimics*). However, over their wide ranges *Papilio* species coexist with a number of other poisonous butterflies and so have adapted genetically to resemble different species in different areas. Also different morphs of the same *Papilio* species may coexist imitating different poisonous species in the same area (see illustration below).

The three butterflies shown on the left are different morphs of *Papilio dardanus*. On the right are three butterflies of different species unrelated to *Papilio*. Each of these species is unpalatable to bird predators. The different morphs of *Papilio* mimic the three unrelated species on the right (from Ehrlich and Holm 1963).

A similar situation exists among large colourful *Heliconius* butterflies in the American tropics. These, unlike *Papilio*, are poisonous, but nevertheless may suffer predation from birds yet to learn that the butterflies are unpalatable. *H. erato* and *H. melpomene*, for example, are widespread and vary greatly in colour pattern over their ranges, yet in any given area where they co-occur the two appear superficially identical. The reason for this is that they are *Müllerian mimics* – resembling each other enhances survival because birds learn more quickly that such butterflies are distasteful. Thus in both *Papilio* and *Heliconius* genetic variability (polymorphism) within species has resulted in widespread local adaptation, yet particular morphs are ecologically well adapted and at a selective advantage only in the particular area where they occur. Elsewhere within the range of the same species they would be at a disadvantage.

divergence) through some combination of mutation, drift and selection, from the moment they originate. Genetic variation, therefore, can be analysed at various levels, from individual differences in the presence of each allele, through population differences in gene frequencies to allele composition in each species or group. The origin

and evolutionary fate of each allele in a population can be likened to the histories of individual characters in a complex story. Much of biology relates to the study of the distribution of organisms in a three-dimensional space, their interrelations and adaptations to their current environment. The study of gene variation and its

evolution adds a fourth dimension (time) to these studies, and through the genetic analysis of populations we may have a better grasp of the origins of species and their adaptations to different environments. It is this understanding of the relationship between genetic diversity and ecological diversity that is of paramount importance for the conservation of biological diversity (see Box 2.2-2).

The patterning of genetic variability within species is rarely concordant with classical taxonomic units below the species level. Even commonly used groupings such as subspecies rarely reflect patterns of genetic variation. Also it is debatable whether the taxonomic ranks are directly comparable between different groups of organisms or even whether it is desirable for them to be so (see, for example, van Valen 1973). In practice, therefore, it will be preferable to discriminate among biological units using the methods, outlined below, that measure genetic variability either directly or indirectly. Results from genetic analyses should be treated with caution, however, if they are not concordant with observed differences in, for example, distribution, ecology or morphology.

A further potential complication in making any assessment of genetic biodiversity within a species is that, with the widespread use of molecular methods in taxonomy, it is becoming increasingly clear that in some groups much 'intraspecific' variability is in fact interspecific and results from the existence of unsuspected cryptic species. This seems to be a particular problem in certain taxa of marine invertebrates, for example, where the adult lacks many taxonomically useful morphological features and is sessile or of low mobility and the larval stage is of short duration and low dispersal capability. The taxonomic simplicity of such species has resulted in many being recorded from several areas and hence having apparent distributions that are very wide and often circumglobal. However, genetic examination often reveals that cosmopolitan species of this type include a number of distinct and sometimes not even closely related cryptic species. For example, Solé-Cava *et al.* (1991) studied genetic divergence between populations of the sponges *Clathrina clathrus* and *C. cerebrum*. Both 'species' are morphologically very distinctive and easily identified by diagnostic characters and both were considered to be of cosmopolitan distribution. In each species samples from Brazil were so genetically divergent from those from the Mediterranean that not only were the populations clearly not conspecific, but their level of divergence approximated to that expected between species from different genera. Cryptic species seem to be most common in morphologically difficult taxa such as sponges (e.g. Solé-Cava *et al.* 1990, 1992), nemerteans (e.g. Rogers 1992; Rogers *et al.* 1995) and certain bryozoans (Thorpe *et al.* 1978a, b), but occur in a wide range of organisms (for

invertebrates many examples are listed by Thorpe and Solé-Cava 1994; see also Knowlton 1993).

2.2.1.1 Analysis of karyotypic variation

The term karyotype refers to the chromosome complement of an individual or of a related group of individuals and is characterized by the number, size and shape of its chromosomes. The analysis of karyotypic variation thus entails studies on numerical and structural polymorphisms (variants) in the chromosome complements of a group of individuals belonging to a particular taxon. Numerical polymorphisms include changes of whole chromosome complements (polyploidy), or of individual (standard) chromosomes (polysomy, monosomy, nullisomy, addition, substitution). Furthermore, changes in the number of supernumerary or B-chromosomes, which are optional extras in addition to the standard diploid or polyploid basic (A) chromosome complement also occur. Structural polymorphisms originate from chromosome rearrangements involving one or more standard or supernumerary chromosomes, such as duplications, deletions, translocations, inversions, misdivisions and Robertsonian interchanges.

2.2.1.1.1 Karyotypic variation analysis techniques. Numerical polymorphisms are normally studied using conventional chromosome staining techniques (Dyer 1979; Sessions 1990). The chromosomes involved in structural rearrangements are recognizable by changed chromosome morphology or by genetic means (linkage analyses). New morphological features of chromosomes include changes of total chromosome length, modified length ratio of short and long arms, and/or positional changes of appropriate cytogenetic markers (chromosome bands, secondary constrictions, late replicating regions, asymmetric bands). The presence of structural changes may also be inferred from the observation of chromosome protuberances and rings in chromosome pairing, telophase bridges and micronuclei.

Chromosome banding is based on a differential staining of chromosomes which results in the resolution of longitudinal bands. The three most important banding methods are Q-, C- and G- banding (Caspersson *et al.* 1969; Commings 1978; Hsu *et al.* 1971; Hsu 1979; Rooney and Czepulkowsky 1986; Sessions 1990). Various specialized banding procedures have also been developed such as fluorescence banding, using various fluorochromes, and nucleolar organizer region (NOR) banding, using silver nitrate (Rooney and Czepulkowski 1986).

2.2.1.1.2 Genetic diversity studies. The analysis of karyotypic variation has often been used to assess genetic diversity within species or gene pools of plants and animals. Genetic diversity studies at infraspecific levels deal mainly with variation found in banding patterns (i.e. Noguchi 1988), in B-chromosome frequency (Hewitt and

Box 2.2-3: Levels of genetic distinction, problems and appropriate tools.

John 1970; Bougourd and Parker 1979; Vujosevic 1992), and in nucleolar organizer regions (Foresti *et al.* 1993; Martinez *et al.* 1993). In other cases, polymorphisms have been recognized using conventional procedures, through the detection of multiple pericentric inversions (Roy *et al.* 1988), translocations and fissions (Lambrot 1988). The analysis of karyotypic variation has been even more extensively used for the analysis of genetic diversity among closely related species (i.e. those belonging to the same genus or tribe) and to study phylogenetic relationships and chromosome changes during the evolution of particular groups of taxa. Polymorphisms detected in these studies are generally based on basic chromosome numbers, polyploidy, B-chromosome frequencies, chromosome size, banding patterns, number and location of nucleolar organizer regions, translocations and inversions (Vosa 1976; D’Emerico *et al.* 1993; Ren and Yu 1993; Svartman and Almeida 1993). In plants, Gramineae is probably the taxon most deeply analysed at the cytogenetic level (Gupta and Tsuchiya 1991). Major studies have also been carried out to characterize the genetic diversity of other taxa of agronomic importance, such as Cruciferae, Fabaceae, Liliaceae and Solanaceae

(Swaminathan *et al.* 1983; Tsuchiya and Gupta 1991). In animals, most in-depth studies have been conducted in Insecta (Orthoptera and Diptera), Amphibia and Mammalia (Rodentia).

2.2.1.1.3 *Assessment.* Karyotypic studies can contribute an array of information independent of the morphological, biochemical, behavioural and other characters that are used for genetic diversity analysis. An advantage of karyotypic analysis over phenotypic analyses is that the variation associated with the former is not so much influenced by environmental or physiological factors. Furthermore, it encompasses several levels of biological organization ranging from the morphological to the molecular, depending on the applicable technology.

In many cases, the main features of the karyotype within a given species are sufficiently constant to allow for the species characterization. Thus, the analysis of karyotypic variation is especially useful in the assessment of genetic diversity among closely related species that share a common gene pool. Genetic diversity studies within and among populations of a given species are, more often, characterized through biochemical and molecular techniques (Baverstock and Moritz 1990).

Box 2.2-4: DNA elements for assessing levels of genetic diversity.

The methods for detecting genetic variation at various genetic markers (described in 2.2.1.2) have provided extremely useful information for the analysis of population structure, levels of gene flow, phylogenetic relationships, patterns of historical biogeography, and analysis of parentage and relatedness. Below are listed a number of important genetic markers and their advantages for assaying genetic diversity within populations.

Mitochondrion or chloroplast DNA

Organelle (mitochondrion or chloroplast) DNA molecules have been exploited for population genetic analyses because these organelles occur in high copy numbers, yet are uniparentally inherited so that each copy is identical. Also, because they are uniparentally inherited, they can offer a unique insight into sex-biased population structure. The chloroplast genome is conserved in most respects with a generally low rate of substitution (reviewed in Palmer 1985, 1987; Wolfe *et al.* 1987; Dowling *et al.* 1990). However, some studies have found significant variation within populations (Soltis *et al.* 1989). Mitochondrial DNA, on the other hand, is highly variable and often used in population level studies (reviewed by Avise and Lansman 1983; Brown 1983; Wilson *et al.* 1985; Avise 1986; Avise *et al.* 1987; Moritz *et al.* 1987; Dowling *et al.* 1990). Typically, there is ample variation within the mitochondrial genome to detect population substructuring and estimate phylogenetic relationships using either RFLPs (e.g. Routman 1993; Georgiadis *et al.* 1994) or nucleotide sequence data (e.g. Edwards 1993).

Y-linked genes

For animals with XY sex determination systems and others (Bull *et al.* 1988), Y-chromosome-linked genes have the potential to serve as independent sex-specific markers. This allows for the partitioning of genetic contributions between the sexes. While in phylogenetic analyses substantial variation has been found among species (Tucker *et al.* 1989), Y-linked genes have not been utilized extensively for population genetic analyses. The substitution rates and independence of gene regions on the Y-chromosome vary greatly among organisms (Pamilo and Bianchi 1993), suggesting that some regions may indeed be useful for population genetic analyses (Tucker *et al.* 1992; Tucker and Lundigran 1993, 1994).

Single locus nuclear genes

Single locus nuclear genes have been used extensively in *Drosophila* genetics (see Crandall and Templeton (1993) for a survey of loci studied). These studies are particularly useful in detecting functional polymorphisms and population structure (e.g. Kreitman and Hudson 1991). The potential of these loci to answer questions relevant to conservation biology and biodiversity has not been realized to date. However, with the growing database of nuclear genes and the awareness of the need for sampling genetic variation at many loci (Wu 1991) for accurate estimates of phylogenetic relationships and overall levels of genetic diversity, these loci will play an increasingly important role in the assessment of global biodiversity.

Multiple copy nuclear genes

Multiple copy nuclear genes, especially the ribosomal DNA repeats, have been used extensively for systematic studies (Dowling *et al.* 1990; Hillis and Dixon 1991). Because they occur in multiple copies, these repeated genetic units are more easily assayed than single copy loci. Additionally, many coding gene regions are conserved, but flanked by non-conserved spacer regions allowing for reliable amplification of the gene region over a broad taxonomic range. The spacer regions often have variation at the individual and population levels offering information on population substructure and levels of gene flow (e.g. Learn and Schaal 1987; Templeton *et al.* 1990). Finally, ribosomal repeat number has been shown to correlate with life-history characteristics in *Drosophila* and has been used to detect processes of natural selection (Templeton *et al.* 1989).

2.2.1.2 Molecular methods for assessing levels of genetic diversity

There is an abundance of molecular techniques useful in surveying the amount of genetic diversity at various loci within species. Below we outline the major techniques being used by practising population geneticists today. Box

2.2-3 indicates the taxonomic levels at which these various techniques are most advantageously applied and Box 2.2-4 outlines some of the methods of analysis available for data generated by these techniques.

2.2.1.2.1 Allozymes. Allozyme electrophoresis involves identifying different protein alleles by their rate of

migration through a gel medium under the influence of an electrical field. The rate of migration of the molecules is influenced primarily by their net charge and molecular weight. Once separated, histochemical staining is used to identify the products of a single gene. The banding patterns obtained can be interpreted genetically (Richardson *et al.* 1986; Murphy *et al.* 1990; May 1992). If an amino acid substitution occurs in a protein molecule this may alter the net charge, or possibly cause conformational changes, and thus alter the rate of migration. Some of the mutations in regions of the DNA coding for one particular enzyme will, therefore, be expressed as enzyme molecules differing in their electrophoretic mobility (i.e. a new allozyme allele). This new allele will initially appear at very low frequencies in the population, so that some rare individuals analysed electrophoretically for the enzyme will be polymorphic (heterozygous) for that allele. The evolutionary fate of the new allele will depend on its relative physiological performance ('fitness', or its 'selection coefficient') and also on chance (stochastic) changes in frequency when passed on to the next generation (genetic drift). Populations evolving independently will, therefore, diverge, as new alleles appear randomly or disappear. Studying the allele differences between populations thus allows us to estimate how much they have diverged.

One of the advantages of electrophoresis is that allozymes are almost invariably co-dominant so that heterozygotes have different phenotypes from the homozygotes. Consequently the calculation of gene frequencies is simple, and these frequencies can then be used for the comparison of populations. Contrary to much of morphological, numerical or chemical systematics, molecular systematics is thus directly linked to the way genes evolve and their distribution in the species. Therefore allozyme electrophoresis not only provides new characters for the study of species, but also brings with it a whole new set of revolutionary tools for their analysis and thus is of great potential value in taxonomy and systematics. A few taxonomic studies have attempted to use electrophoretic patterns as taxonomic characters without any genetic interpretation; for example, by merely scoring bands as present or absent. Such approaches disregard the genetic information content and thus much of the value of the data and are also likely to be open to dispute on theoretical grounds. There are several earlier general or more specific reviews of the systematic uses of electrophoretic data (e.g. Gottlieb 1977; Ferguson 1980; Thorpe 1982; Buth 1984; Hartl *et al.* 1990; Hillis and Moritz 1990; Thorpe and Solé-Cava 1994; Solé-Cava and Thorpe 1995).

In taxonomic or systematic studies the genetic data produced by electrophoresis can be used by systematists to answer two types of questions:

1. Are the samples from which genes are being compared from the same freely interbreeding gene pool? or
2. How great are the differences between the gene pools being compared?

Clearly the answer to Question 1 is appropriate for distinguishing species (alpha systematics) and that to Question 2 can be used to provide data on interrelationships of taxa (beta systematics or phylogenetics). However, data on levels of difference between gene pools can also be used to give an indication of whether these are likely to be conspecific. In systematics Question 1 above would commonly become 'are these two biological entities (e.g. morphotypes, colour morphs, subspecies) from the same or different species?'. Enzyme electrophoresis is at its most powerful in answering such problems, particularly when the two entities are sympatric. From conventional definitions under the biological species concept (and also for the phylogenetic species concept; Cracraft 1983, see also Templeton 1989), two sympatric morphs should, if conspecific, be part of the same evolutionary unit. In other words, they should have (given certain assumptions and within the limits of expected and calculable sampling errors) the same gene frequencies at each locus. Clearly, samples of different morphs that are conspecific should be freely interbreeding and therefore be different only at the loci coding for their morphological difference and perhaps some closely linked loci. Even if these morphs were subject to some sort of assortative mating or strong selection pressure, the gene frequencies over all the other gene loci should, because of recombination, remain similar (Wright 1978). Main assumptions are that gene frequencies are not altered by postzygotic selection or by individuals with different gene frequencies migrating in from elsewhere. Given these assumptions significant variation at any locus, between two sympatric populations, demonstrates a barrier to gene flow and at least partial reproductive isolation. In sexually reproductive, routinely outbreeding organisms, this indicates the likelihood that two populations should be regarded as different species. Available evidence suggests that selection is unlikely to cause major problems. Although many workers over the last 20 years or more have devoted a great deal of time and effort trying to demonstrate the effects of natural selection on the frequencies of electrophoretically detectable alleles at enzyme loci, it is far from clear that these alleles are, under natural conditions, commonly influenced by selective forces. The extensive literature covering the putative effects of selection on allozyme loci (reviewed by, for example, Nei 1987) indicates that resultant

differences are rarely, if ever, marked or even unambiguously detectable. It is thus improbable that any observed level of genetic differentiation of sympatric morphs will result from selection alone.

Migration of individuals to give mixed gene pools is generally more of a theoretical problem than a practical problem. Allopatric populations if reproductively isolated may be expected to diverge genetically over a period of time and eventually to accrue clear differences in gene frequencies at various loci. However, an almost inevitable feature of any model of allopatric genetic divergence is that (except with most improbably strong selective pressure) almost any degree of migration (as low as one individual per generation, irrespective of population size; Wright 1978; Nei 1987; Maynard Smith 1989) or gene flow between populations will preclude divergence. Herein lies the problem for the idea of the possible mixing of genetically diverged populations, because, if they are close enough for individuals to coexist anywhere within their dispersive range, it would be extremely unlikely that at least a minimal amount of gene flow could not occur between them and thus genetic divergence would be most unlikely to have occurred in the first place (see Todd *et al.* 1991; but also see Palumbi 1992).

It should be remembered that allozyme data cannot show that two morphs are conspecific, only that no significant differences could be found. It is always a possibility that differences existed, but were not found.

2.2.1.2.2 Restriction fragment length polymorphism (RFLP). Restriction endonucleases are highly specific enzymes which cut a molecule of DNA wherever a particular nucleotide sequence occurs. When the DNA is digested with a restriction enzyme the DNA will be cut into fragments. Different individuals may well have differences in nucleotide sequence and may produce a different number of restriction fragments which can be separated by electrophoresis. This polymorphism in restriction sites forms the basis of the study of RFLPs. Restriction sites can be gained or lost through mutation.

The important feature of RFLPs is that gains or losses of restriction sites will behave in a Mendelian way and can be detected through the electrophoresis of the DNA fragments. If the total DNA from one organism is digested with a restriction enzyme, the number of fragments generated will be too large to be analysed. Smaller regions of the genome are generally studied.

RFLP analyses provide character data in one of two types (Swofford and Olsen 1990). The first type occurs when the RFLPs are mapped to specific locations within the gene region being examined, resulting in restriction site data. The restriction site data are a direct assay of the underlying nucleotide sequence data resulting in a genotypic assay. However, because the mapping of

restriction sites can be difficult and time-consuming (Murphy *et al.* 1990), researchers often treat the presence or absence of the restriction fragments of a given length as character states (i.e. restriction fragment data). While restriction fragment data are more easily obtained, they suffer from the potential of violating the assumption of independence among characters critical to phylogenetic analyses (Swofford and Olsen 1990). Thus, when restriction fragment data are obtained, they assay a phenotype which may or may not accurately reflect the underlying genotype or nucleotide sequence pattern.

RFLP has largely been used in three ways:

1. Using large amounts of purified organelle DNA. Organelle (mitochondrion or chloroplast) DNA molecules can be purified and, after electrophoresis, the restriction products are stained with ethidium bromide. This method usually involves working with large amounts of fresh tissue (freezing makes the separation of mitochondrial and nuclear DNA more difficult; White and Densmore 1992). The mapping of the restriction sites on the molecule is facilitated by its relatively small size; an additional advantage is the knowledge now accumulated on the organelle genome of many organisms (Gold *et al.* 1993; Smolenski *et al.* 1993). A limitation of this approach is that, at present, it is not applicable to nuclear DNA.
Since organelles are usually transmitted through the female, organelle DNA will be transmitted maternally. The organelle haplotypes will not, therefore, behave in a Mendelian way, the population being constituted of clones of female-to-female inheritance lines. This means that organelle DNA may give false information about population structuring, especially in species where dispersal is different between males and females (Avice 1994).
2. Visualization of RFLP fragments with molecular probes. The total DNA of the organism can be digested with restriction enzymes, but then methods are needed to look at just a small proportion of the fragments. This approach is similar to that used for allozymes, where after the electrophoresis of total soluble proteins only a few are visualized (stained). With the probe technique the differential visualization of homologous regions of DNA is achieved through the electrophoresis of DNA fragments and their transfer to a membrane ('Southern blotting'), which is then hybridized with pieces of cloned DNA ('probes') for one given region of the genome. These DNA probes can be radioactively or chemically labelled for subsequent identification using autoradiography or specific stains. The probes can be stripped off the membrane, which can then be re-probed for another region

of the genome. This method is sensitive and relatively simple, but depends on the availability of suitable probes (Aquadro *et al.* 1992; Stabile *et al.* 1992; Tegelstrom 1992). It can be used for nuclear genes.

3. RFLP on DNA fragments generated by PCR. Because of the large amounts of DNA produced by PCR (polymerase chain reaction; see below), the results of the subsequent use of restriction enzymes can be visualized directly on an agarose gel stained with ethidium bromide. Primers must be designed for homologous regions of the genome (Hoelzel and Green 1992; Arnheim and Erlich 1992; Holland 1993), and these are then used to amplify fragments, which are then cut. A small number of restriction sites is likely to be found, and analysis is straightforward (see Karl *et al.* 1992; Karl and Avise 1993). This approach is the fastest and the simplest, since it does not require cumbersome procedures for organelle DNA purification, nor does it require Southern blotting or hybridization/detection processes. It does, however, require adequate primers, the production of which can be laborious. Once the primers have been designed, though, data can be acquired quickly and relatively inexpensively, so that population analysis becomes feasible. This method also is applicable to nuclear DNA.

2.2.1.2.3 Multi-locus DNA fingerprinting of minisatellite loci. The most common use of RFLP is, as outlined above, to provide genetic markers, either with maternal inheritance (as with mtDNA) or with a Mendelian segregation (with nuclear DNA). In order to be able to interpret the restriction patterns genetically, the number of bands produced has to be limited. Sometimes, however, it may be desirable to detect individual differences (e.g. in the study of family or clonal structure). In this case, emphasis is put on detecting large numbers of very highly variable loci. This technique has been called DNA fingerprinting (Jeffreys *et al.* 1985; Pemberton and Amos 1990), and usually involves the Southern blotting of RFLP fragments and their probing with non-specific probes (see Bruford *et al.* 1992). There are difficulties in interpretation due to the very large number of loci visualized and the possibility of dominance, since the smaller fragments are usually not visualized.

2.2.1.2.4 Single-locus DNA fingerprinting of minisatellite loci. This technique is similar to that above but uses single loci with variable numbers of tandem repeats (VNTR). It has been applied to both 'minisatellites' and 'microsatellites'. The main advantage is that gene frequencies can be calculated, and standard population genetic methods used to analyse the data.

2.2.1.2.5 Gene cloning and polymerase chain reaction (PCR). One of the basic needs in molecular biology is for

the production of large amounts of a small part of a DNA molecule. This DNA will then be used directly for population genetics (through RFLP analysis or sequencing) or as a probe to detect homologous regions of DNA of other individuals (e.g. Southern Blotting analysis, described above). Until recently the usual technique for DNA amplification was recombinant cloning, which is the insertion of a chosen DNA fragment into a plasmid or viral genome ('ligation'), and the insertion of this plasmid or virus into actively reproducing bacterial cells ('transformation'). During bacterial cell replication the plasmids or viruses will also reproduce, so that in a few generations the inserted DNA will have been reproduced thousands of times. The plasmid DNA is then extracted from the bacterial cells and excised with specific restriction enzymes, which cut the DNA close to the insertion point. The inserted segment can then be separated from its carrier plasmid by gel electrophoresis, or it can be used directly for sequencing. This method is unlikely to be practicable for routine screening of large numbers of organisms.

Another way of amplifying DNA is by replication *in vitro* using DNA polymerase. This occurs using several cycles of denaturing (separating the two strands) of the DNA molecule through heat (DNA polymerases use single-stranded DNA as a template), cooling it down for annealing with specific primers and the synthesis of a new DNA fragment, so that, in one cycle of some 3–5 minutes the number of copies of the region of the DNA between the two primers (one for each strand) is doubled. If the cycle is repeated many times, large numbers of copies of the DNA fragment will be produced.

This use of polymerases for *in vitro* cyclic DNA replication is known as the Polymerase Chain Reaction (PCR) (e.g. Saiki *et al.* 1985; Innis *et al.* 1990; Arnheim and Erlich 1992; Hoelzel and Green 1992). The technique of PCR is conceptually and technically simple, and the difficult aspect is designing the right primers for the genes to be studied (Holland 1993). Another difficulty is the optimization of experimental conditions (Innis *et al.* 1990; McPherson *et al.* 1993).

PCR is extremely sensitive, so that contamination can be a major problem and therefore exacting procedures to avoid contamination are required (Kwok and Higuchi 1989; Longo *et al.* 1990; Sarkar and Sommer 1993).

One of the advantages of PCR-based analysis is that the amount of DNA needed for the amplification is extremely small (Li *et al.* 1988). Thus PCR can be used to amplify DNA from preserved tissues (Shiozawa *et al.* 1992) or from small larvae (Silberman and Walsh 1992; Corte-Real *et al.* 1994a). An additional advantage is that in rare or protected species molecular analysis can be done in a non-destructive way (Whitmore *et al.* 1992).

There are several ways in which PCR can be used for population analysis (Avise 1994). The products of the PCR

can be cut with restriction enzymes for RFLPs (see above), the products of the PCR themselves may be variable in length, or PCR products can be sequenced (see below). The largest difference between applications, however, is to be found in the strategy for the development of primer systems. In this case, three main alternative approaches are available.

1. Use of homologous primers. Species-specific primers (i.e. primers with exact, homologous, matches of sequence) can be designed using laboratory sequence data derived from a genomic library (Warner *et al.* 1992; Karl and Avise 1993), from sequence data available from the literature or from gene data banks, or from the sequencing of PCR products initially produced with heterologous primers for ubiquitous genes. For conserved sites the problems of non-specific amplification are largely avoided (Hoelzel and Green 1992). Population analysis can then be carried out via RFLP or sequencing of PCR products obtained through primer systems designed for exons of protein-coding genes (McVeigh *et al.* 1991) or for conserved rDNA regions flanking a highly variable non-transcribed spacer (Martin *et al.* 1992; Wenink *et al.* 1993). Homologous primers can also be designed for conserved regions flanking microsatellites (large numbers of repeats of short nucleotide sequences, which are separated and visualized directly; Warner *et al.* 1992). They can also be designed for conserved regions of exons flanking introns, which are less affected by natural selection and therefore have more gene variation which can be useful for population genetic analysis (Corte-Real *et al.* 1994b).
2. Use of heterologous primers. Some regions of the genome are evolutionarily highly conserved (Nei 1987). This makes it possible to design primers for a population analysis in one species using sequence data published for homologous regions of the genome in other species (Hoelzel and Green 1992; Holland 1993; Karl and Avise 1993). They are termed heterologous because sequences are not generally identical.
3. Use of random primers (the RAPD technique). As a result of the tolerance of PCR to mismatches between primers and the DNA template, principally at lower temperatures (30–35 °C), short arbitrary sequences of nucleotides can be used to amplify random fragments of DNA. This technique is called the analysis of 'random amplified polymorphic DNA' (RAPD; Welsh and McClelland 1990; Williams *et al.* 1990). Usually RAPD analysis produces a large number of fragments, many of which are individual-specific. Since RAPD is a PCR-based technique, it can be used to work with very small

amounts of tissue. If inheritance is verified, RAPD patterns can also be used for population genetics (Chapco *et al.* 1992).

2.2.1.2.6 Nucleotide sequences. Nucleotide sequences of either DNA or RNA offer the greatest genotypic resolution as these methods survey the nucleotides themselves. Nucleotide sequences can be obtained either by direct sequencing of genomic DNA using specific primers to amplify (via PCR; Saiki *et al.* 1988) targeted regions of the genome or by cloning regions of interest and sequencing from the cloned fragment. The most commonly used method of sequencing is the Sanger dideoxy method (Hillis *et al.* 1990). While nucleotide sequencing allows for a direct assay of the DNA or RNA sequence, a limitation of the method is that it only surveys a small proportion of the genome relative to, for example, restriction site surveys. Nucleotide sequencing also tends to be one of the most expensive methods of surveying genetic diversity. The trade-offs between cost, amount of genetic material surveyed, and desired resolution all depend upon the questions being addressed (see Box 2.2-3).

2.2.1.2.7 Applications of PCR. As the DNA sequences of more and more genes from various species of animal and plant become known the number of loci available for PCR analysis will increase. It is very likely that over the next few years PCR population analysis will become at least as popular as allozymes for population genetic studies. RAPD is a useful technique for the identification of strains of algae or other asexually produced organisms (Patwary *et al.* 1991), and for the identification of individuals to species that are otherwise difficult to separate (Crossland *et al.* 1993).

2.2.1.2.8 Conclusions. Molecular techniques are more expensive than most ecological or morphological approaches to the study of genetic or species diversity and consequently such methods should be used only where other techniques are less powerful or not feasible, not merely because they may be considered less up-to-date. Molecular population genetics has always been a scientifically fashionable field, but the favoured techniques have changed from allozyme electrophoresis in past decades, to PCR, RFLPs, RAPDs and sequencing in the 1990s. This has, not surprisingly, been detrimental to collaboration between different fields. Nowadays there is a drive to use DNA-based techniques to approach population genetic problems, even when simpler techniques (such as allozyme electrophoresis) can give the same information, at a fraction of the price. This may have an important effect on the funding policies of scientific research particularly in Western countries, but it is simply the result of timing and historical context. The main reason is not that DNA techniques are necessarily better but rather, that they are new. As Avise (1994) has pointed out:

Imagine, for the sake of argument that DNA sequencing methods had been widely employed for the past 30 years and that only recently had protein-electrophoretic approaches been introduced. No doubt a headlong rush into allozyme techniques would ensue, on justifiable rationales that (a) the methods are cost-effective and technically simpler, (b) the variants revealed reflect independent Mendelian polymorphisms at several loci scattered around the genome (rather than as linked polymorphisms in a single stretch of DNA), and (c) the amino acid replacement substitutions uncovered by protein electrophoresis (as opposed to the silent base changes often revealed in DNA assays) might bring molecular evolutionists closer to the real stuff of adaptive evolution.

It is important to assess objectively the advantages and disadvantages of each technique before deciding which to use. Allozyme electrophoresis is a well-established technique for evolutionary or population work, and nowadays its use is simple and straightforward. An indication of how mature an experimental approach has become is the type of papers published using it: recent papers using allozyme analysis tend not to have the word allozymes in the title, and are 'problem oriented'. On the other hand, many papers using DNA technology have the words DNA, PCR or RFLP in the title and are 'technique oriented'. Not surprisingly, many of those papers are just basic descriptions of levels of gene variation with one method or another (like many early allozyme studies). It is likely that, as they become simpler and better understood, DNA methods will simply join the rank of 'good techniques for the right problems', together with allozymes. It is not unreasonable to predict that RAPDs and DNA fingerprinting will probably occupy a niche within the study of individual variation; RFLPs of PCR-amplified DNA will become well established, together with allozymes, for population genetic work, and, assuming further reductions in time and cost, DNA sequencing will be used in both population genetics and phylogenetics.

2.2.2 Patterns of differentiation under domestication

Crops and ornamental plants, livestock, pets, and the microorganisms involved in the fermentation of foods and drinks are all domesticated organisms that have arisen by evolution from wild organisms. Much research has concentrated on the origin of domesticates, benchmarks being studies by de Candolle (1882) on plants, and by Geoffroy Saint-Hilaire (1861) on animals. Darwin himself used knowledge derived from breeding domesticates, particularly domestic pigeons, for examples of genetic variation and changes that occurred in response to selection (Darwin 1859, 1868).

Domestication is the inclusion of wild species populations, wholly or in part, into human society. This is a gradual process which is coincident with and followed by genetic changes brought about by the changed selection pressures. At the beginning a wild organism is husbanded: a wild plant is cultivated, a wild animal is kept captive, or attaches itself to a human community, a wild yeast is cultured. But the continued husbandry of many generations has an impact on the organisms themselves. Whether this is occurring consciously or unconsciously on the part of the humans involved, the husbandry process exerts a selection pressure (*artificial selection* as contrasted with *natural selection*) that causes a shift in the genetic make-up of the organism. So those populations of a species husbanded by humans undergo evolution both towards more reliable husbandry (e.g. easier germination in crop plants, tamer behaviour in large mammals) and towards greater yield of the desired product, be it the seeds of cereals, the milk of livestock or the alcohol of yeast. In some cases the organisms become profoundly different from their wild forebears, and totally dependent on humans both for husbandry and reproduction. Wild and domestic populations demonstrably conspecific, as shown by breeding tests, have frequently been given different Latin binomials which confuses both nomenclature and a proper appreciation of the real biosystematic relationships. Domesticates can truly be said to be human cultural products.

The processes of domestication apply to particular populations of the species manipulated by specific populations of humans. So whilst a population is being domesticated in one area, the original wild species can persist elsewhere, at least for a while. Thus for many so-called *domesticated species*, domestication generates genetically differentiated human-controlled races within the species. For example, both garden peas as a world-wide crop, and wild pea populations, coexist in the species *Pisum sativum*. Similarly the vast range of domestic dogs are conspecific with their wild forbear the wolf, *Canis lupus*, although for convenience the former is known as *Canis familiaris*. The patterns of variation discernible between peas (petit pois, marrowfat, mange-tout, forage-peas, etc.) are consequences of genetic variations between man-made races of *Pisum sativum*; the pattern in dogs (alsatians, poodles, pekinese, etc.) is comparable: these are man-made genetic races of *Canis familiaris*. In other cases the *wild progenitors* may have become extinct so that all known examples of a species are of the domesticated races. For instance many variants of the faba bean *Vicia faba* are known (e.g. broad bean, tick bean, horse bean), but in this case the species is today unknown in the wild, as is the Arabian camel *Camelus dromedarius*. The wild ancestor of cattle, the aurochs, is known to be extinct.

Early horticulture and agriculture could have developed from gatherer cultures by a set of practices, beginning with

Box 2.2-5: The domestication syndrome in crop plants (Schwanitz 1966; Harlan 1975; Simmonds 1979; Hawkes 1983).

Character change	Significance
Gigantism	Affects the part of the plant utilized – seed, fruit, root, stem, tuber – an almost universal characteristic of domesticated crop plants.
Suppression of dispersal mechanisms	Results in retention of seed in the fruit or inflorescence; reduction of stolon length in potatoes, resulting in concentration of harvestable product and facilitation of collection. Another virtually universal character.
Suppression of sexual reproduction	Crops reproduced vegetatively by tubers, e.g. potatoes show this. In the special case of the banana its culture as an edible fruit depends on this. It serves to concentrate assimilates in the production of the harvested product.
Changed growth form	May be a consequence of gigantism – larger fruit require structural support, allometric growth changes may result. Plant growth habits become more restrained and less rampant, facilitating crop husbandry.
Changed life-form	Short-lived perennials (e.g. <i>Phaseolus</i> beans) may become biennial or annual, often in response to selection for higher yield and earlier maturity. The energy required for perennation can be diverted to production of biomass usable by humans.
Changed breeding system	Self-pollination has advantages in reducing weather-dependence for pollination, promoting yield stability in areas with unpredictable weather conditions.
Loss of seed dormancy	Promotes predictability in production of good crop stands and highly advantageous in cultivation. Short-term dormancy is useful in moist climates inhibiting sprouting in the ear of cereals and seeds in pods of legumes.
Biochemical changes	Commonly involve loss of toxic or distasteful compounds, glucosinolates in Brassicas, cucurbitacin in cucurbits, cyanogenic glycosides in Lima beans and cassava, lectins and protease inhibitors in some legume crops.
Changed ploidy level	May be auto- or allopolyploidy. Autopolyploid grasses (e.g. <i>Lolium</i> spp.) are cultivated. Allopolyploidy is more significant, has resulted in production of essentially new species such as the bread wheats and many soft fruit novelties (<i>Rubus</i> spp.).
Physiological changes	Photoperiod requirements can limit extension of the range of crops which originate in low latitudes at high elevations. A change to day neutrality can enable this to occur as in <i>Phaseolus vulgaris</i> , the common bean.

protecting individuals (e.g. wild fruit trees, baobab, oil palm), eliminating undesirable species in semi-natural habitats, allowing some roots to remain in the soil after collecting (e.g. wild yams), and deliberate planting of crops in ploughed or hoed fields. From the Neolithic period c. 10 000–1500 BP, humans have imposed both conscious

and unconscious selection for such traits as ease of harvest, storage ability, high and reliable germination rate, and enhancement of parts of the plant being consumed (including improvement of taste and texture). Many of these selection pressures have been conscious, but some are simply due to the effects of cultivation practices, such as

Figure 2.2-3: Vavilov’s world centres of origin of cultivated plants (Vavilov 1951). Stars indicate centres of form origination of the principal cultivated plants; dotted areas indicate chief centres of origin of cultivated plants (Hawkes 1993).

non-shattering and non-dormant seeds, or adaptation to day-length. With the development of crops morphologically and physiologically distinct from their original wild progenitors, many cultivated plants have become increasingly distanced genetically from their wild relatives. In the case of cereals, the basic domestic traits are controlled by relatively few linked genes, forming a ‘domestication syndrome’ (Harlan 1975; Pernès 1983): in other crops it can be more complex (see Box 2.2-5).

In this century, Vavilov (1951) was the first to study extensive collections of cultivated plants, allowing him to elaborate his theory of centres of diversity which he equated with centres of origin (see Fig. 2.2-3). Subsequent research on several crops showed that in some cases, secondary centres of diversity existed, and that many crops did not fit into the original scheme. Harlan proposed a modified concept, distinguishing real centres of origin of limited area, and large ‘non-centres’ where crops and techniques could have spread later in history (Harlan 1975; Zeven and de Wet 1982). Whereas present researchers now see domestication as a process of biological evolution interacting with human practices and cultural traits, the popular success of the ‘centres of origin’ concept may lead to some misconceptions because it ignores phenomena such as transdomestication (Hymowitz 1972) and history, and

also underestimates the role of farmer societies outside the centres.

It is not easy to define a domesticated animal. Many wild animals may be tamed as babies or juveniles but generally revert as adults to the wild pattern of behaviour towards humans, often in a dangerous and unpredictable way. Domesticated animals have been selected so that such wild patterns have been suppressed to a greater or lesser degree, as in domestic cattle for example. A domestic animal is one that has been bred in captivity for purposes of economic profit to a human community that maintains complete control over its breeding, organization of territory and food supply (Clutton-Brock 1987). The first domesticated animal was the dog, followed by the major livestock species: cattle (both taurine and humped (zebu), sheep, goat, pig, horse and ass), and all these are thoroughly assimilated into human culture. Clutton-Brock (1987) distinguishes the cat, Asian elephant, camelids, reindeer, water buffalo and the Asiatic cattle other than the zebu, as ‘exploited captives’. The rabbit and ferret and many rodents and carnivores including fur-bearers form another stratum, the small mammals. Finally many species, including the cheetah and many deer and antelopes, are or have been the subject of game farming or experimental domestications. The distinctions among these strata are essentially on the basis of the closeness of the human–animal relationship and also on the degree to which

Box 2.2-6: The domestication syndrome in animals (Clutton-Brock 1987).

Change	Significance
Change in body size	Reduction in body size is an initial change brought about by domestication: subsequently the trend may be reversed. At the present time many breeds of dog are smaller than wolves, but some are larger.
Polymorphism of pelage and external features	External features in wild animals, e.g. the rabbit, tend to be uniform: domesticated breeds vary in pelage, carriage of the ears, eye colour. In cattle an enormous range of size and conformation of horns is found.
Internal characters and dentition	Fat deposition subcutaneously is a feature of cattle, sheep, pigs and other domesticates. Brain size is reduced and the structure of the skull changes, resulting in shortening of the jaw and reduced size of the teeth. Muscle ridges on bones and facets for articulation of joints are reduced, due to the lower level of physical exercise they take.
Behaviour	Changes in behaviour tend to be neotenic in nature, e.g. retention of juvenile patterns: this makes domestic animals more submissive and more easily managed than their wild counterparts.

morphology and behaviour have been modified by captive breeding for human advantage, thus bringing about divergence from wild ancestors (see Box 2.2-6). The process of domestication is not fully understood and attempts in recent years to domesticate wild species have been only partly successful. Almost certainly (Clutton-Brock 1987) in prehistoric times the taking of baby animals from the wild, their rearing in human society and the retention for breeding of those that showed themselves adaptable to these conditions would have played a part in domestication.

Domesticated microbes include microbial variants or strains used to make antibiotics and vaccines, as well as those traditionally used to make bread and wine. Fermentation has been used since 5000 BC as a means of producing alcohol and various foods (Nisbet and Fox 1991). Like some domesticated animals and plants, some microbes used in the manufacture of food or other products have retained their capacity for feral return to the wild (Davis 1987).

Weeds and commensals must also be included in discussion of domesticated organisms. A weed is defined by Harlan and de Wet (1965) as ‘a generally unwanted organism that thrives in habitats disturbed by man’. Commensal animals and microorganisms under a very similar definition may associate directly with humans (as parasites, diseases or domestic pests), or with domesticated plants or animals (as crop or livestock diseases or pests). They too undergo a parallel domestication process – that is, selection for success in the same human-made environments, and the only difference is that humans have had no intention of husbanding them. The important point is that in some cases there has been a subsequent reversal

of roles and a weed or pest subsequently becomes a preferred domesticate: the crop plant rye originated from a weed in this way, and a number of pests, such as pigeons, rats and mice are now used by humans in a variety of positive ways for sport (e.g. racing pigeons) and for research (laboratory rats and mice).

Lastly, feral plants and animals are domesticated forms that have escaped and maintain themselves in the wild without intervention by humans. The term is not normally applied to such species as the fox or rabbit in Australia; these are more accurately described as introductions. Feral populations may be seen as genetic resources, or as pests threatening native flora and fauna, and their value in genetic conservation remains speculative (Hall 1990). Nevertheless it would be wrong to exterminate such populations without characterizing them unless they are causing harm to endemic species populations through competition or predation. An excellent example of a problematic feral population is the wild cattle of Amsterdam Island in the South Indian Ocean. This population is genetically distinct and worthy of conservation as a rare breed but it has devastated the vegetation of the island and threatens unique seabird populations. A management plan has been devised which conserves the cattle but also protects the environment.

2.2.2.1 Characterizing biodiversity within domesticated species

The biodiversity within domesticated species is of interest for two quite different reasons. First, the process of

domestication has led not only to the evolution of new variation, but in many cases to a proliferation of new forms and a range of forms far beyond the variation in the original progenitor wild species. Examples would be the breeds of dogs (from alsatians and rottweilers to pekinese and poodles) or the botanical varieties of *Brassica oleracea* (kale, cabbages, cauliflowers, broccoli, kohlrabi and brussels sprouts). Secondly, because this variation is in already domesticated forms, it is available and more easily utilized than that in related, non-conspecific organisms elsewhere in the range of biodiversity. So, for instance, new food and industrial products are more easily developed from domesticated soya bean than from wild legumes, or, in the research world, laboratory races are more easily developed from commensals (pigeon, rat, mouse) than from wild animals. Indeed this feature is illustrated by the number of domesticated organisms already used for more than one purpose: *Linum usitatissimum* for fibre and oils; *Cannabis sativa* – fibre and drugs; Sheep – today wool, skins, milk and meat, but formerly also for fat and horn, and tomorrow possibly the commercial production of pharmaceuticals, hormones, etc., in the milk of transgenic animals.

The system for naming and classifying the races of domesticated organisms varies widely between plants, animals and microorganisms. The differences reflect not only different professional traditions, but also major differences in the breeding systems and thus the genetic patterns that arise.

In most cases domesticated races are within a species whose ancestors originated in the wild: exceptions are the products of interspecific and occasionally intergeneric hybridization, chimaera formation and gene transfer by biotechnology. So cultivated peas are within *Pisum sativum*, the wild pea, and the yeast used in the fermentation of beer is within the species *Saccharomyces cerevisiae*. Exceptions to this are interspecific hybrids such as the hybrid tea Roses and the mule *Equus caballus easinus*.

In plants, despite the enormous range of breeding systems, the individual precise race is always called a *cultivar*, the word originating from *cultivated variety* (Brandenburg 1986; Styles 1986). However, there are broad traditionally named groupings of cultivars within most domesticated plant species. The most widespread term for these is *cultivar group*, although in some parts of the world a more detailed hierarchy, such as *convar*, *provar*, etc. is used (Jirasek 1966; Parker 1978). A *cultivar* is any group of cultivated plants recognized as a distinct entity in production, utilization and trade. It usually bears one or more distinct common names in a popular language. The word 'cultivar' has been introduced by the International Code of Nomenclature for Cultivated Plants in order to distinguish it clearly from the botanical variety, or varieties, governed by the ICBN. A cultivated plant species may be split into several botanical varieties, but

those varieties may well include both one or more cultivar groups and a great many cultivars. Those involved in the creation and control of new cultivars tend to restrict the use of the term cultivar to a population which is 'distinct, homogeneous and stable', and use the term 'landraces' for the heterogeneous populations previously grown. It is easier to speak about modern cultivars and old or traditional ones.

Cultivated varieties have been named for a very long time, but they were given by horticulturists rather than botanists. Most breeders, especially hybridizers of horticultural plants, give appropriate or imaginative vernacular names to the many new forms of plants they create. In 1862, Alphonse de Candolle recommended that a distinction be made between the names of cultivated and wild plants, but the first Proposals for an International Code of Nomenclature for Cultivated Plants were adopted only in 1950 and published in 1952 (Stearn 1953). This shows how difficult it is to reach a consensus between groups having different traditions and needs. In later editions, the code has been extended to cover agricultural crops and forest trees. It is this code that lays down the rules for naming cultivars and cultivar groups. A series of institutions were nominated by the International Society for Horticultural Science to manage living reference collections and to compile lists of cultivar names. But in the meanwhile, industrial countries had begun establishing regulations for the seed and plant trade. Enforcement of these regulations can be effective only through the use of agreed names, and so regulatory authorities are now playing a leading role in naming cultivars. There are two sets of regulations. The first regulates the commercialization of a cultivar through registration in an official catalogue, which comes under public law. The other protects the rights of the breeder, and comes under private law; it is governed by an international convention (UPOV). In both cases, cultivars must follow technical requirements summarized under the acronym DHS or DUS (distinctiveness, homogeneity, stability or distinctiveness, uniformity, stability). A new cultivar must be distinct from existing cultivars; it must be homogeneous in the sense that differences between individuals must be limited, and stable in the sense that it remains the same through several generations. As to the names of cultivars, some countries have allowed them to be protected as trademarks, whereas others do not. As breeders wanted to have this kind of legal protection, especially in the case of vegetatively propagated plants where no technical protection is available, the practice prevailed of giving two different names to cultivars. The official cultivar name is sometimes a mere code, beginning with three letters indicating the breeder, while the name known by the public is effectively a trademark.

In history, a cultivated species could spread in different regions and continents and diverge with a very small

probability of merging again. Groups of cultivars could then develop and become sufficiently distinct to be given taxonomic status. With the globalization of our society, much initiated by Europeans, interchanges of domesticated plants have accelerated. Breeders now have access to the global gene pool of crops, former differentiation patterns are being blurred. A great number of hybrids have been produced, but information about their pedigree is often scarce. What remains is a set of ideotypes that breeders have followed to fit the needs of production and trade based largely on loosely defined cultivar groups.

Different forms of domesticated animals are known as *breeds*. For a variety of reasons these are often less precisely defined and less distinct than cultivars in plants. A breed is defined as follows (Clutton-Brock 1987): 'a group of animals that has been selected by man to possess a uniform appearance that is inheritable and distinguishes it from other groups of animals within the same species'. The numbers of breeds or breed varieties of the main livestock species in the world, as enumerated by Hall and Ruane (1993) are: ass 80, water buffalo 74, cattle 1085, goat 400, horse 515, pig 481, sheep 1196. It is not known what proportion of the present diversity of breeds has arisen in the very recent past, and what in the 10 000 years or so since domestication. Certainly, the main breed groups, at least of cattle, became distinct very early (Loftus *et al.* 1994a, b). The present-day distribution and abundance of breeds has been interpreted in terms of human geography (Hall and Ruane 1993); world-wide, the most populous countries have the most breeds, suggesting that conditions favouring the growth of human populations have also favoured the differentiation of breeds. This suggests that the more complex the requirements for livestock products and the more complex human society, the more the diversification of breeds.

2.2.2.2 The genetic basis of cultivars and breeds

Plant-cultivars differ greatly according to their breeding system and mode of propagation. In the case of self-fertile plants, traditional cultivars are populations consisting of a mixture of lines and their crosses; the first modern cultivars were pure lines taken out of populations, and maintained their genetic integrity substantially from one generation to the next. In the case of outbreeding plants, traditional cultivars or landraces are populations with self-incompatibility and other traits that favour outbreeding; modern cultivars may be populations where some traits have been fixed and are maintained by mass selection, or increasingly, F1 hybrids, which are the product of the first generation of crosses between two pure lines. This solution allows a high level of homogeneity of the crop, and a technical protection for the breeder, as planting the seeds of the second generation will lead to segregation of characters and the growing of a

heterogeneous crop. Other common types of cultivars are clones, which are the genetically identical descendants of one individual, and are reproduced by vegetative propagation. This propagation can be achieved by natural means, such as by production of tubers (potato, cassava, yams) and bulbs (garlic, tulip), stolons (strawberry), lateral shoots (date palm, banana), or by grafting (most fruit trees). Apomictic plants are a particular case where seeds are produced without pollination, reproducing identically the genotype of the mother. Modern clones may be obtained by *in vitro* multiplication (tissue culture). Examples include roses, poplars and orchids.

Outwardly many traditional livestock breeds are very heterogeneous. Many of the breeds listed by Mason (1988), the standard directory to the livestock of the world, are described as having diverse coat colours, horn shapes, etc. Generally in traditional husbandry, because of harsh conditions, any female that survives is used for breeding and human selection for, say, uniformity of coat colour is an unaffordable luxury. In some cases, an array of colour variants may be chosen deliberately for identification, aesthetic or religious purposes. For some livestock, natural selection may be important – Finch and Western (1977) report that in Kenya, cattle with light colour are favoured in very hot environments.

In spite of this outward heterogeneity, traditional breeds are probably relatively uniform in many other ways (conformation, physiological adaptation, etc.), and though critical studies are lacking, it is probable that within-breed variation is less than between-breed variation. Under benign conditions, such as in Britain since the eighteenth century and France since the nineteenth century, selection for uniformity could be practised, and attempts made to improve the mean performance of the breeds thus defined (Hall 1990, 1993; Audiot 1995). The result has been breeds responsive to increased inputs and better care, which were genetically uniform and when crossed with other breeds would impose their characteristics on the latter (an attribute known as prepotency). An example is how the British cattle breeds Shorthorn, Hereford and Aberdeen Angus were crossed with the range cattle of North and South America (themselves descendants of Spanish cattle imported by the followers of Columbus). Within a few generations, the hardy but unproductive range cattle had been changed, by repeated crossing, into good beef cattle, with the outward appearance of British cattle, yet retaining, it is presumed, sufficient genes from their Spanish ancestors to confer local adaptation.

The development of Western breeds was made possible by the use of pedigree registers (herd-, flock- or stud-books) to provide certification of authenticity, and by the use of breed standards whereby only animals conforming to a defined type could be registered. This might suggest the term 'breed' would have different definitions for such

'Western' livestock and for traditional livestock, yet the basic definition (Clutton-Brock 1987) is applicable to both, provided it is understood that by 'appearance' what is meant is not simply coat colour.

It is important to understand the genetic basis of breeds so that appropriate methods of conservation can be deduced. It has been suggested that rates of mutation are sufficiently high that in a numerically large breed there is an adequate supply of new genetic material (Hill 1982); also that an effective way of conserving animal genetic resources is not to concentrate on breeds but to select, from a pool of animals, for biological extremes (for instance to develop lines of extreme fatness and extreme leanness or of very high and very low prolificacies). However, resources are unlikely to be made available for such programmes. Advances in transgenics and biotechnology mean, in principle, that a gene could be transferred into any breed to improve some attribute (but see Hall 1990), but in practice success is not guaranteed because a gene may perform well in one breed but fail when transferred into another. Consequently, the general view is that the most useful unit of variation in animal genetic resources is the breed. The accepted reason for conserving breeds is that new requirements may arise in the future which cannot be met by those breeds currently popular.

Of the seven main livestock species, probably at least 350 breeds outside Europe are in danger of extinction, and about the same number within Europe (Hall and Ruane 1993). Major priorities for research are: (1) the further investigation of the world's breeds, particularly of the less well described species, to make a complete list of those in danger and of the threats facing them, and (2) to understand the genetic relationships among these breeds so that conservation efforts can be targeted effectively.

Hall (1993) suggested that a criterion of taxonomic distinctiveness should be used to determine a priority list for conservation efforts: an alternative view might be that only breeds that are likely to have commercial significance in the future should receive conservation support, but there has been a surprising lack of discussion. What is certain is that there is a very large number of locally adapted breeds, that have evolved in their own particular environments, and which possess productive and adaptive characteristics about which, in most cases, we know almost nothing.

Strains or lines are particular genetic stocks maintaining a particular gene or combination of genes. Practically, they are to be found in species of generally small body size, short generation interval and high reproductive rate, which can tolerate inbreeding depression without causing high losses. Examples include experimental animals of medical interest (such as white mice), small farm animals such as poultry and Chinese carp, and pets such as the pigeon. With advances in biotechnology, strains of genetically engineered animals (such as some new forms of rabbit) are of growing importance.

F1 hybrids, a comparatively recent development in plant breeding, have been a feature of some livestock systems for many decades. The advantageous features of two distinct breeds can be combined in a crossbreed (Hall 1990), which is used not for reproduction of its own kind but for the production of a particular marketable commodity.

2.2.2.3 *Species complexes and gene flow*

As many related plant species are able to exchange genes, the gene pool of a crop plant can be augmented by this process of introgression. Harlan and de Wet (1971) distinguished two levels at which this could occur, and recognized three distinct gene pools (see Box 2.2-7). The primary gene pool is formed by all the plants that may be crossed freely with the target crop. It is synonymous with the biological species (Mayr 1963). The secondary gene pool includes those plants which may be crossed with the cultigen and give fertile hybrids. This could include some closely related species. The tertiary gene pool is formed by plants which cannot be used in classical crosses, but only by techniques such as *in vitro* embryo rescue, protoplast fusion or genetic transformation.

The above approach is crop-centred. It has been reformulated and enlarged by Pernès (1984) with the concept of the species complex. 'Two plants belong to the same species complex if they are able, in natural conditions and with some probability, to exchange genes by hybridization, whether directly or through the use of intermediate plants'. Within a species complex, compartments (or boxes) are distinguished. 'Two plants belong to different compartments if there exist some limitations to the success of their spontaneous hybridization.'

The important scientific issue is that hybridization is no longer considered as an exception, or even a contravention of the natural order, but is understood to have an important functional role in the evolution of living beings, wild as well as domesticated. Even a very low level of hybridization is sufficient to ensure a significant gene flow between populations.

Research on the structuring of genetic diversity is important for knowledge as well as for breeding, as hybrids may be used as bridges in gene transfer. As a result, some components of a complex may be given a taxonomic status at the rank of species or subspecies. Others may not, as is the case with the sexually reproducing diploid forms of *Panicum maximum* and its apomictic tetraploid forms, which may occur in the same area and share the same morphological characters, although belonging to different compartments.

Species complexes may include crops, weeds and the wild relatives of crops. One classical example is the situation in centres of origin, where the wild relative may be found growing with the crop, at the margins of fields, or as a weed in the field itself. Gene flow is important, but

Box 2.2-7: Genetic resource profiles of crop species (Smartt 1990).

Harlan and de Wet Category	Constituents	Order of recourse and accessibility to breeders
GP1 – primary gene pool	(a) Cultigen	1st order
	(b) Weedy form	2nd order
	(c) Wild prototype	
GP2 – secondary gene pool	Cross-compatible species producing ± fertile hybrids	3rd order
GP3 – tertiary gene pool	(a) Cross-compatible species producing viable but sterile hybrids	4th order
	(b) Cross-compatible species producing inviable hybrids.	5th order
(Quaternary gene pool)	Incompatible related species	6th order

The gene pools are ranked in terms of the accessibility of their germplasm through traditional hybridization methods: these embrace the first three gene pools. Gene transfer from 4th to 6th order gene pools would require biotechnological intervention. Not all orders and suborders of gene pools exist in all crop species. In some legume crops there is no third order gene pool (*Phaseolus lunatus*, *Glycine max*) and in some species (*Vicia faba*) there is neither a second nor third order gene pool. The presence or absence of these gene pools and an empirical estimate of their magnitude could be useful for planning the collection, conservation and utilization of germplasm resources.

strong disruptive selection pressures maintain both populations as distinct. They have commonly been given taxonomic status as distinct subspecies or varieties. The species complex approach is of particular interest for crops, but may be applied to wild plants as well.

2.2.2.4 Future developments

In traditional agrosystems, farmers collected their own seeds or kept their own livestock, and by so doing, natural selection pressures could act. In modern systems, seeds are bought, and legal and technical regulations lead to stability and homogeneity of cultivars, which means that cultivars are not allowed to evolve naturally. Evolution takes place only through the replacement of old by new cultivars. The reservoir for evolution will lie *ex situ* in gene banks, *in agro* in the regions of the world where traditional agrosystems are still operating, and *in situ* where populations of wild relatives are maintained: however, new methods of dynamic conservation are being investigated.

Animal breeds have generally maintained a high level of variability up to now. But with ongoing development and refinement of techniques such as artificial insemination, embryo transfer and cloning, their genetic structure may change rapidly, and make conservation measures necessary. The protection of living populations (*in situ* conservation in this context) should be backed up by *ex situ* (cryopreservation) programmes (Hall 1990).

2.2.3 Investigating genetic diversity

Diversity within and among species has traditionally been assessed using morphological, behavioural and karyotypic characters. As addressed in the previous chapter and elsewhere (Hillis 1987), these traditional characters have both advantages and disadvantages over more modern molecular techniques. Particularly in the within-species case, the levels of variation for these morphological characters are typically too low to be of great utility. Molecular data, however, use characters that evolve at typically higher rates, but with a great diversity of rates represented at different loci within the genome (Maynard Smith 1989). Consequently it is important to match the level of taxonomic resolution (or the expected amount of divergence between the groups studied) with the evolutionary substitution rate of the gene or DNA region to be studied. Several different molecular techniques exist which offer different degrees of resolution in assays of population level genetic diversity (Boxes 2.2-4 and 2.2-8). Because these techniques survey different levels of genetic variation, they have greatest utility at different levels of hierarchical relationships within species (Box 2.2-3).

Any molecule of DNA will accumulate mutations through time. The difference between regions is the rate at which the accumulation will proceed. If the region of the DNA is conservative (i.e. accumulates new mutations more slowly), there may not be enough variation in the molecule

Box 2.2-8: Analytical techniques for use with within-species molecular data.

Within-species phylogenetic reconstruction

Intraspecific phylogenies are useful tools for testing a variety of hypotheses relating to biodiversity issues, from assessing species status to examining correlations between populations and geographic distributions. Traditional phylogeny reconstruction methods (e.g. maximum parsimony, maximum likelihood, neighbour joining, etc., see Swofford and Olsen (1990) for a review) have often been applied to within-species data sets. However, within-species data sets violate many of the assumptions of the traditional methods of phylogenetic reconstruction (Crandall *et al.* 1994). For example, in the intraspecific case, ancestral nodes tend to remain in the population. Interspecific phylogeny reconstruction techniques assume that these ancestral taxa no longer exist in the population. Recombination is more likely to pose a problem for the intraspecific case when nuclear genes are used. Most traditional methods ignore recombination. Finally, multifurcations are a common feature of intraspecific phylogenies, whereas most interspecific phylogeny reconstruction techniques assume bifurcating phylogenies. Templeton *et al.* (1992) have developed a method of phylogenetic reconstruction that takes into account these difficulties. It is based on a population genetic model of divergence which incorporates the shared characters as well as differences to establish relationships. This method is extremely powerful, even when the number of character differences between individuals is small (Crandall 1994).

Measuring population structure

The extent to which a species is subdivided into genetically differentiated subpopulations is an important component of many issues in conservation biology and population genetics. Wright (1951) first developed indices for the amount of population subdivision based on allele frequencies, *F-statistics* (reviewed in Weir 1990: Ch. 5). These indices have been expanded by a number of authors for use with restriction site or nucleotide sequence data and with microsatellites (Nei 1982; Lynch and Crease 1990; Slatkin 1995). Most recently, Hudson *et al.* (1992a) have developed a statistical test for detecting population subdivision based on the analysis of sequence data. They also provide information on the power of this statistic relative to other methods and sample sizes, amount of migration, mutation and recombination.

Rates of migration

The estimation of rates of migration is important in assessing genetic diversity of subdivided populations because it can inform the researcher of the extent to which subdivided populations will maintain that subdivision and the role of migration in the creation of genetic diversity. Migration rates can be estimated by directly monitoring gene flow among populations or by indirect measurements based on genetic divergence (Slatkin 1987). When the direct estimates of gene flow do not correspond to the indirect estimates, large-scale demographic changes can be inferred. Recently, two new techniques for estimating rates of migration have been developed; the first based on phylogeny (Slatkin and Maddison 1989) and the second based on *F-statistics* (Hudson *et al.* 1992b). The relative strengths and weaknesses of each method for different types of data are discussed in Hudson *et al.* (1992b).

Detecting natural selection

The extent to which natural selection has influenced substitutional patterns at various loci can provide valuable information to the conservation biologist. Using nucleotide sequencing data, Hudson *et al.* (1987) developed a statistical test to detect the influence of natural selection. McDonald and Kreitman (1991) later developed an alternative test which requires fewer assumptions about the underlying evolutionary process. Their model has been expanded upon by Sawyer and Hartl (1992).

for population analysis. On the other hand, if the region accumulates mutations too quickly it may become saturated (i.e. new mutations will occur in the same places as earlier ones), and the information available in the molecule will be difficult to interpret. With DNA fingerprinting analysis, for example, the number of alleles at some loci can be so large that the sample sizes that are necessary for obtaining any statistically meaningful gene frequency data are often huge and consequently impracticable for most studies (Bruford *et al.* 1992). It is very important, therefore, that the right

techniques be chosen for the degree of taxonomic resolution necessary. At the level of the individual (e.g. paternity/maternity studies, clonal structure) the emphasis will be in working with high degrees of genetic variation. Good techniques here are combinations of allozyme genotypes at polymorphic loci, DNA fingerprinting, and RAPDs. At the population level, appropriate resolution may be obtained through the analysis of allozymes, RFLPs and nucleotide sequence data. These data are also useful for interspecific comparisons and hybrid zone analyses.

2.2.3.1 Type of biological material available

The size of the organism, and how it can be collected (or how much of it) are important considerations when planning a molecular study of organisms. Work with allozymes, for example, can be used only with material that is fresh or has been frozen soon after collection. Single locus DNA analysis, on the other hand, principally if using PCR, can be done even with samples fixed in alcohol or air-dried (Shiozawa *et al.* 1992). Many organisms produce large amounts of mucus or have many allopathic secondary metabolites, and allowance must be made, in each study, for the optimization of the DNA or allozyme extraction techniques (Kumar *et al.* 1988; Lohuis *et al.* 1990). When working with small organisms (Walsh and Starkweather 1993) or larvae (Graves *et al.* 1990; Silberman and Walsh 1992; Corte-Real *et al.* 1994a) or endangered species with extremely small remaining populations, PCR-based methods are particularly powerful, since they require only minute amounts of tissue.

2.2.3.2 Research and development

There is a basic difference between allozyme and DNA methods in respect of the costs associated with the structure of the work. In the case of allozymes the whole process of the development of tools for the acquisition of data and the application of these tools is integrated. The highest running costs of allozyme electrophoresis are at the final stage of the population analysis (i.e. the biochemical stains for the different allozymes). Consequently individual allozyme laboratories are usually independent and have all means of production for their work. Development costs are generally small, since most allozyme techniques have been thoroughly tested and new enzyme stains can be incorporated more or less directly from descriptions in the literature. Work with DNA, on the other hand, often involves two distinct processes: the development of tools and their use in population analysis are quite separate, and, unlike allozyme electrophoresis, the higher costs are in the beginning of the work, not at the stage of data acquisition. High costs are usually associated with the design of species-specific primers for PCR, or with the production of homologous probes for RFLP analysis. These phases often necessitate DNA cloning and/or gene sequencing, both of which are expensive and labour intensive. Once the primers and probes have been developed, and experimental condition optimized, genetic data can be obtained quickly and at relatively little additional cost.

Ultimately, this separation between designs of primers and probes (i.e. construction of the means of production) and data acquisition (i.e. labour-intensive use of the means of production) stimulates collaboration between different research groups. Laboratories well equipped for molecular biology can be efficiently used for primer design or probe production, processes requiring only a few individuals of

the population studied. Subsequently, these primers/probes can be used to study specific problems best tackled in laboratories better equipped for fieldwork and with a strong background in ecology or population genetics. As DNA sequence data accumulate for a large number of species it will become easier to design primers directly from published sequences and the need for cloning and sequencing will be reduced. However, there will remain a need for close collaboration between molecular and other biological laboratories to identify areas of study and to correct problems.

An important consideration when choosing the best technique to be used to study a problem is time. A typical allozyme laboratory can produce gene frequency data for up to six gene loci for up to 100 individuals in one (long) day. A molecular laboratory will take much longer because of the need to extract and purify DNA, which takes about two days for up to 50 samples. Once the DNA is purified, many PCR analyses can be carried out in a day (it takes about 4 hours to run a PCR, and typically about 20–50 samples can be handled simultaneously). RFLP analysis is limited by the time required for the digestion of the DNA molecules with the specific endonucleases, usually between 2 and 14 hours, with the number of samples that can be analysed dependent on the number of buffer tanks available. In the case of the PCR/RFLP association they have to be made sequentially, so it will take about three days to produce RFLP data for one locus for 100 individuals. Because of this and the high cost, most DNA-based work to date has concentrated on approaches that require smaller sample sizes (e.g. phylogeny or specific evolutionary problems). This situation will probably change as the costs of molecular methods fall, and it is likely that eventually population molecular studies with DNA will commonly use the sort of sample sizes currently practical for allozymes.

2.2.4 Case studies of the use of genetic techniques in studies of within-species and between-species diversity

2.2.4.1 *Partula*

The land snail genus *Partula* comprises approximately 100 species distributed throughout the Marquesas, Society, Austral and Marianas archipelagos of Polynesia and Micronesia. Their variability and microgeographic genetic differentiation, insular habitat, low mobility and ease of handling have enabled the population genetics and evolutionary history of *Partula* to be studied extensively since the early 1960s (White 1978; Cowie 1992). The group is undergoing (or has recently undergone) speciation. The majority of studies, focused on analysis of detailed morphological data taken from a suite of shell characters illustrated in Figure 2.2-4, have revealed no apparent

Figure 2.2-4: A shell of *Partula*, showing the points from which measurements were made. AA', length of shell; BB', width of shell; CC', length of aperture; FF', width of aperture; AH, length of spire; KK', width of spire; JJ' width of upper suture; A'C', width of lip; LL', height of shell; AL', height of spire. (Reproduced from Murray and Clarke, 1980.)

correlation of genotype to environmental variables (White 1978; Cowie 1992). Such work has been combined with reproductive data from laboratory and natural populations to place up to 11 ‘species’ of *Partula* from the island of Moorea in the Windward group of the Society Islands into two species complexes: members of each complex show variable levels of reproductive isolation depending upon the ‘interspecific’ partner and the geography. Whilst clines and hybrids occur at some localities, these species coexist in other areas with no apparent introgression (Clarke and Murray 1969; Murray and Clarke 1980). Partulids represent an unusual situation amongst land snails in that some species exhibit both dextrally and sinistrally coiled shells (Cowie 1992). This has fuelled detailed discussion about the genetics of coiling and its role in isolating mechanisms (Johnson 1982; Johnson *et al.* 1990) and the possibility of single-gene speciation (Orr 1991). The enormously detailed and painstaking studies of the structuring of populations of *Partula* on Moorea provide arguably the most detailed

Figure 2.2-5: A phylogeny for species of *Partula*, a Wagner tree based on allozyme frequencies at 22 loci. The horizontal distances are proportional to the inferred amounts of change. (Reproduced from Johnson *et al.* 1986.)

assessment of the ways in which evolution has fitted an animal to different ecological requirements within a restricted geographical area (Murray *et al.* 1982, 1993).

In agreement with the morphological variability, allozyme data have revealed *Partula* to be highly polymorphic, the exception being *Partula gibba* which frequently self-fertilizes (Johnson *et al.* 1977). The genetic identities (I) for conspecific and congeneric comparisons are high compared to expected values from Thorpe’s (1982: p. 151) compilation (Johnson *et al.* 1986). A lack of genetic differentiation is expected given that speciation is still in progress and gene flow still occurs between some species by way of hybrids (see Murray and Clarke 1980). Using allozyme data from 24 *Partula* species (including 22 from the Society Islands) and six related species (Partulidae), a phylogenetic tree (see Figure 2.2-5) was constructed and used to infer a biogeographical history for the partulids of the Society Islands (Johnson *et al.* 1986). A monophyletic origin for Moorean species is consistent with results from detailed morphological, reproductive (Murray and Clarke 1980) and karyotypic (Scvortzoff 1966, in Johnson *et al.* 1986) work. Indeed there is a consistent general pattern of speciation by radiation within islands (with the exception of *Partula turgida*, for which there was only one specimen). Whilst this provides support for models of parapatric speciation, molecular methods will undoubtedly have to be employed to confirm the exact

Figure 2.2-6: Aggressive posturing between males of *Anolis carolinensis*. (Reproduced from D. Crews, 1978. In: *Behaviour and Neurology of Lizards*, Greenberg, N. and MacLean, P.D. US Department of Health, Education, and Welfare, National Institutes of Mental Health, Rockville, Md.)

speciation mechanism given the high allozymic similarities of the species. It appears that the Windward partulid species arose by a single colonization from the Leeward Islands and that the Tahitian species arose by radiation after a single colonization from Moorea, a scenario compatible with the known geological history of the Society Islands. Interestingly, the allozyme data also suggest that the ancestral partulids first arrived on the youngest Leeward island, Huahine (Johnson *et al.* 1986). In this sense partulid speciation is virtually unique among well-studied island-dwelling species whose radiations appear mostly to have involved multiple colonizations (Murray *et al.* 1993).

Whilst allozyme data have been used successfully in elucidating a sequence of island colonization and phylogeny in conjunction with more traditional morphological and geological techniques, clearly some problems of speciation and biogeography will probably only be resolved by more detailed molecular studies in suggesting a monophyletic origin for Tahitian partulids (Johnson *et al.* 1986). The complex variation in mitochondrial DNA patterns, however, suggests that parallel, reversed or convergent evolution may be partly responsible for the morphological variation, implying a monophyletic origin of Tahitian partulids (Murray *et al.* 1991) and thus supporting the allozyme data.

Unfortunately, the introduction of a predatory snail, *Euglandina rosea*, has caused the extinction of all wild *Partula* species on Moorea, and other island species are under threat (Murray *et al.* 1988; Murray 1993). The only way forward for the study of partulids and their role in Pacific biogeography is to protect the few secure wild populations and to attempt DNA extraction from the extensive museum collections (Cowie 1992).

2.2.4.2 *Anolis*

The iguanid lizard genus *Anolis* (illustrated in Figure 2.2-6) offers an effective case study of the successful application

of a range of genetic techniques to the pattern of diversity within and between species. The genus is of considerable ecological importance, being distributed throughout tropical America and the Caribbean and comprising over 200 species, many of them restricted to particular islands. The classification of these species was based originally on osteological data (Ethridge 1960) which were later presented as a formal classification by Williams (1976). The presently accepted phylogeny (Roughgarden 1989; Roughgarden and Pascala 1989) was derived from these data combined with additional information based on the immunogenetic assay of albumins (Gorman *et al.* 1971, 1980; Shochat and Dessauer 1977, 1980), karyotypes (e.g. Gorman and Atkins 1969) and electrophoresis of proteins (e.g. Yang *et al.* 1974; Gorman *et al.* 1980).

Anolis was among the first genera for which detailed studies of population levels and allele frequency analyses were published (Webster *et al.* 1972; Wright 1978). Allele frequencies from four populations of *Anolis carolinensis* from the United States and South Bimini in the Bahamas were re-analysed by Wright to produce estimates of his fixation coefficient (Wright 1978: p. 273). Another study (Webster and Burns 1973) detected sibling species in *Anolis brevirostris* from Haiti. This was an early example of a now routine application of electrophoresis in systematics.

Soulé *et al.* (1973) compared levels of morphological variation and the average heterozygosities of protein products of 20–21 gene loci in eight *Anolis* species. In showing a significant correlation between the morphological and electrophoretic data they provided evidence that a sample of as few as 20 loci could give a reliable estimate of the genetic variation within a population. Their research group also studied the phylogenetic relationships between these eight species (Yang *et al.* 1974), which are distributed on various southern Caribbean islands. The interspecific genetic distances (*D* of Nei 1972) reported between these

congeneric species were highly variable, ranging from 0.013, which is unusually low for an interspecific comparison, to 0.973, a relatively high value for congeners.

The description of a hybrid between *A. grahami* and *A. lineatopus neckerri* (Jenssen 1977), included reference to unpublished allozyme data generated by T.P. Webster that added powerful support to the diagnosis of the hybrid on morphological and behavioural grounds by Jenssen himself. Gojobori (1982), incorporated heterozygosity estimates from 14 *Anolis* species into a study of the effects of enzyme function on the levels of polymorphism observed at their coding loci. These data, which are discussed by Kimura (1983), showed that heterozygosity levels were generally low at loci coding for enzymes with various functional constraints.

More recently, DNA-based molecular techniques have also proved useful to *Anolis* biologists. Hass *et al.* (1993) incorporated DNA sequence information from a mitochondrial ribosomal RNA gene into a study of the relationships between two putative genera *Chamaelieolis* and *Chamaelinorops* within *Anolis*. Their data led them to conclude that both taxa are recent derivatives within *Anolis*. *Anolis* has also been used to test the assumption of selective neutrality in the mitochondrial genome (Malhotra and Thorpe 1994). On the Lesser Antillean islands of Dominica and Guadeloupe there are morphological clines in *Anolis oculatis* and *A. marmoratus* respectively. Both islands are similar in age, orientation, topography and climate and show parallel ecological zonation. Sequencing of part of the cytochrome *b* gene by Malhotra and Thorpe showed that variation in this region of mitochondrial DNA exhibits a stepped-clinal change congruent with the morphological and environmental clines. They suggest that the logical interpretation of such data is that selection is acting at the molecular level. The authors, however, accepted that such a claim would be contentious and are continuing their research.

Thus the papers on *Anolis* by several groups of workers from the 1970s onwards have provided us with a detailed case study. Techniques ranging from conventional skeletal anatomy to various molecular methodologies have been combined to give a unique insight into the ways in which species and populations of *Anolis* have changed with evolutionary and geographical divergence.

2.3 Biodiversity from an ecological perspective

2.3.1 Introduction

Species of plants, animals, fungi and microorganisms are not distributed uniformly over the surface of the world but form spatial patterns of various sorts. There are three groups of reasons for this: they may occur together or apart for (1) historical reasons, (2) causal reasons and (3) functional reasons.

The historical reasons are studied mainly in historical biogeography, which is concerned with listing the effects on distribution patterns of events that happened in the past. For example, after the tectonic break up of Pangaea, many

species were unable to cross the newly originating oceans. Because of their isolation, they evolved independently on either side, enhancing the total diversity of life. The same happened when mountain ranges were thrown up, or at much finer scales of space and time when lakes, deserts, forests, glaciers, or water currents temporarily partitioned the surface of the Earth.

Temperatures, precipitation and soil conditions, for example, are not evenly distributed over space, but form intricate, ever-changing patterns. The species, responding specifically to these factors, follow the changes, and find themselves grouped together with other species preferring the same conditions and separated from those adapted to different ecological factors. Thus, Arctic and boreal species are adapted to low temperatures and often high humidities, being unable to live in Mediterranean or tropical conditions. This also holds for finer levels of adaptation, causing them to live only in certain parts of the tundra region. When climatic conditions change, they shift their distribution in order to follow the change and often increase or decrease their range of distribution, becoming either more cosmopolitan or rarer.

When species live together in a certain area, they may interact to various degrees, thus forming communities in which different species fulfil different roles within the community process. Thus, there are primary producers, producing organic materials from nutrients in the soil and the atmosphere with the help of light. Herbivores as secondary producers live on the primary ones, bacteria and plants, and are eaten by tertiary producers, i.e. predators, parasites and disease organisms. At different levels, saprophytes and their zoological counterparts enter the system to consume dead material.

Complicated patterns of species clumping may originate from the operation and interaction of these three types of factors: historical, causal and functional. Sometimes only few species are found occurring together within a certain area, whereas in other areas many are found. Thus the diversity of life, or biodiversity, is heterogeneously distributed. This chapter structures and characterizes biodiversity from an ecological perspective under two main headings – the diversity within areas of the spatial patterns, and the diversity between areas.

2.3.2 Diversity within areas

2.3.2.1 Species richness and species diversity

The central single measure of ecological diversity is species richness or α -diversity (see Box 2.3-1): we count the number of species using only their presence (and not abundance) in a given area. Ecologists from northern countries often talk with admiration of the diversity of tropical rain forests or coral reefs. The unusual richness of many tropical areas can be quantified simply by some measure of within-area species richness. Colombia and

Box 2.3-1: Definition of alpha (α), beta (β) and gamma (γ) diversity.

The division of diversity into alpha (α), beta (β) and gamma (γ) components, to characterize diversity on different scales, was first proposed by Whittaker (1960, 1972). Alpha diversity and gamma diversity pertain to the number of taxa at local and regional spatial scales respectively, and their units are number of species or other suitable measures of diversity. They are thus inventory diversities, following Whittaker (1977). Beta diversity measures the turnover of species between local areas and is usually treated as a dimensionless constant, or differentiation diversity (Whittaker 1977; see Section 3.3.2.2.3). Distinguishing these components of diversity goes hand in hand with quantifying the local distribution of species, similarity among local assemblages, and rate of change in species composition with respect to distance or ecological condition.

Alpha (α) diversity is *within-area diversity*, measured as the number of species occurring within an area of a given size (Huston 1994). It therefore measures the richness of a potentially interactive assemblage of species.

Gamma (γ) diversity is also a measure of *within-area diversity*; however, it usually refers to overall diversity within a large region (Cornell 1985a) and its comprehension has direct connotations with dealing with biodiversity at the landscape level (Noss 1983; Franklin 1993). Gamma diversity has no upper limit but most often it refers to a whole region or country, rarely to a continent. Regional species lists, often the only information available, can only be treated as lower bounds on gamma diversity. Cody (1986, 1993) has used gamma diversity as the turnover of species between different localities within the same habitat type, as with distance between sampling areas. This corresponds to beta diversity in more common usage. As yet, definitions of alpha and gamma diversity have not been settled (e.g. Latham and Ricklefs 1993) and, owing to the continuousness of ecological scale and to the different sizes and spatial distributions of different organisms, this probably is not even feasible.

Beta (β) diversity was introduced by Whittaker (1960) to designate the degree of species change along a given habitat or physiographic gradient. As such it is a measure of *between-area diversity*. It cannot be expressed in numbers of species because it is a rate or proportion: it is normally represented in terms of the similarity index or of a species turnover rate.

The simplest definition of beta diversity is the ratio of the gamma diversity of a region to the average alpha diversity of local areas within the region, hence:

beta [dimensionless] = gamma [taxa]/alpha [taxa]

Other measures of beta diversity have been proposed, and each of these responds in different ways to sample size (Wilson and Shmida 1984; Magurran 1988; Harrison *et al.* 1992); some of them require additional information (Cody 1986; Schluter and Ricklefs 1993).

Two aspects of beta measures should be considered before they are applied to field data. First, although originally intended to measure the rate of species turnover along a continuous gradient (Wilson and Shmida 1984; Cody 1986), beta diversity is generally used to estimate average changes in species among discrete sites or habitat units. In this case, beta is not really a rate measure, but instead more a measure of average sample, or community dissimilarity.

Second, interpretation of beta diversity depends on whether it is used to compare ecologically similar or distinct kinds of sites. When used to compare similar sites, possibly of different sizes, it measures the proportion of species from a wider environment actually occurring in a sample site: it may thus be used to indicate the area needed to include a certain fraction of diversity in that environment, or the effect of adding sites to a protected area. In the latter case, the beta component of diversity measures community response to habitat heterogeneity.

Kenya, for example, are home to over 1000 species of birds, while Britain and the deciduous forests of eastern North America are home to only about 200. A coral reef off northern Australia may be home to 500 species of fish, while the rocky shoreline of Japan may be home to only 100 species. These simple ‘species per country’ statistics are useful, but they fail to capture the full measure of biodiversity for several reasons.

First, for many groups of species, what we know for certain is only that we do not know many, perhaps even the majority, of the species present. Consequently, species richness can only be measured for some but not all the species in an area. Only in very few places on the planet are there rough estimates for the total number of species. Second, the size of the area will often be arbitrary. Species richness is related to area in a complicated way, so we must

exercise caution in comparing the diversities of areas that differ greatly in size. Third, there are issues involving the weighting of species richness according to the perceived value of the species.

Why is it, and how is it, that so little is known? Does it matter that so little is known? When good data are available for the distribution of richness, one can assess how well what we know about the diversity of one group (say butterflies) correlates with the diversity of another group (say birds). If the diversity of one group predicts the diversity of another, then a forest's diversity can be characterized from just its birds or plants, a reef's diversity from its corals, or a lake's diversity from its fish. Even within one group of species there is a choice of measures of within-area diversity.

2.3.2.1.1 Comparing diversity across species groups: coherence of patterns. How do the patterns of species richness in one group of species correlate with those in another? If the answer was always to be 'very closely', then ignorance of the species in some taxonomic groups might be less critical, for we would expect that these groups too would follow the same pattern. Certainly, there are some broad correlations across the groups we do know, reassuring us that the gaps in our knowledge might not critically alter the answers to some general questions. For instance, the tropics are generally richer than comparable temperate habitats. Tropical Lake Malawi has 245 species of fish, while Lake Windermere (England) has only nine (Barbour and Brown 1974). Indonesia ranks second, first, sixth and eighth in the number of species of endemic mammals, birds, reptiles and amphibians, respectively (World Conservation Monitoring Centre 1992). In contrast, Britain has few or no endemic species in any of these four groups. Simply, the richness of the tropics is well established for many different terrestrial groups. Tropical seas likewise hold high numbers of gastropod and bivalve mollusc species.

There are enough exceptions for us to be cautious about all specific patterns. Oceanic islands may have unique and diverse birds and plants but have very few mammals. (The obvious reason is that birds and plants can reach there more easily.)

When we have excellent data, such as the mapped distributions of many plant and animal groups in Britain, we can formalize this analysis. Prendergast *et al.* (1993) asked if the locations in Britain that are rich in flowering plants, liverworts, birds or mammals, were also rich in *all* of them. They are not. Areas rich in liverworts are not rich areas in birds, and vice versa. Areas rich in butterflies are different again. At a continental scale, Schall and Pianka (1978) compared the numbers of species of frogs, lizards, turtles, snakes, birds and mammals found in 1° latitude \times 1° longitude blocks in North America and Australia. In Australia, areas rich in frogs were also areas rich in

everything else, except for lizards. In North America, areas rich in frogs were also rich in turtles and snakes, but were poor areas for birds and mammals.

These complicated patterns emphasize that there can be no short cuts to understanding the patterns of diversity. Areas rich in one group of species need not be rich (and indeed may be unusually poor) in another group. And even when there are correlations in richness on one continent, the correlation can be reversed on another.

2.3.2.1.2 Comparing areas of different sizes. Even when we restrict our characterization of diversity to one group of species, it is not always easy to make comparisons between different places. Plant ecologists often count the number of species in 0.1 ha, and many species mapping schemes are on 10 km squares, or $1^\circ \times 1^\circ$ latitude–longitude squares (c. 100 km squares). Microorganisms may be counted on scales of square centimetres. Simply, there is no internationally agreed spatial scale over which we measure richness. It varies from one group of species to another. Even for well-known groups of species, species richness is often reported by country and countries differ very greatly in size. So how do we compare our species counts when they are undertaken at such different spatial scales?

The detection of diversity is clearly scale-dependent. Sampling over progressively larger areas will lengthen species lists: as a progressively larger area is sampled the increase in the number of individuals and habitats sampled leads to more species being recorded. However, the number of species does not increase with area in a simple way. Per unit area, Ecuador has more species of land birds (1435 species in 300 000 km²) than Canada (426 species in 10⁷ km²). Both these values are much less than 1 species per km². A hypothetical island off the coast of Canada would certainly be home to several species of birds and so more species per unit area: however, no-one would think the island intrinsically richer than Ecuador. Simply, our basic measure of diversity – richness per unit area – is not a good way of comparing areas of widely different sizes. That measure is too strongly influenced by the size of the area.

Ecologists have long known that the relationship between the number of species (S) and the size of an area (A) is often quite well described by $S = cA^z$, where $z = 1/4$ and where c depends on the group of species we choose (MacArthur and Wilson 1967). Roughly, an area 16 times as large as another one should hold twice as many species.

Ecologists know that the value of the parameter z is not always $1/4$ – it varies between 0.15 and 0.8. For example, the values of z are generally higher for real islands than for sampling areas (islands) of the same size within larger regions of similar habitat (McGuinness 1984). None the less, the simple rescaling of area using the $1/4$ power of area can often be a useful 'rule of thumb' in comparing the diversity of different countries. Ecuador's greater number of bird species compared with Canada does not properly

Figure 2.3-1: Raunkiaer's plant life-form spectra (from Archibold 1995).

capture the difference in diversity, as Canada is so much larger. And richness per unit area favours small areas. Species per $(\text{area})^{1/4}$ is rather cumbersome, but it does provide a rough means of comparison. Thus, relative to what we expect from their areas, Ecuador (61 species per $(\text{area})^{1/4}$) is approximately eight times richer than Canada (7.5 species per $(\text{area})^{1/4}$).

2.3.2.1.3 The relative abundance of species. One of the most striking features of ecological communities is that species vary in their abundance. For example, a few species may be extremely common, a slightly larger proportion fairly common, with the rest (the majority) occurring only infrequently. It is conventionally assumed that the diversity of a community rises (even if the species richness does not change) as the abundances of the species become more equal. Thus, if there are two hypothetical communities each containing four species and 100 individuals, community A (with each species having 25 individuals) will be deemed to be more diverse than community B (where the four species have very different abundances of 97, 1, 1 and 1 individuals). The evenness (or equitability) of a community is a measure of how equal the species abundances are.

A number of measures, such as the well-known Shannon (Shannon and Weaver 1949) and Simpson (Simpson 1949) indices, take account of the relative abundances of species. However, this type of 'combination' index can be difficult to interpret. In addition, many of these indices make assumptions about sampling that may be difficult to meet. For these reasons ecologists often prefer to report the measurements of the two components separately. Such an approach can be very powerful since parallel information on species richness and evenness can provide important insights into the ecological changes that occur over time

(such as those following eutrophication or deforestation) or the differences between ecological communities (such as tropical and temperate forests).

Data on the abundances of species can be time-consuming or impractical to collect. For this reason these diversity measures tend to be useful in only a relatively small number of well-studied areas. Magurran (1988) provides a book-length review of diversity indices and the relative weightings of the components of species richness and evenness they provide. Any diversity measure (such as the evenness measures) that de-emphasizes species richness implies that rare species are less valuable than others.

2.3.2.2 Taxic diversity

A limitation with species richness and species diversity measures is that they treat all species equally. It may sometimes be useful or interesting biologically to explore other perspectives in which species make rather different contributions: *taxic diversity* (this section) and *functional diversity* (2.3.2.3, below) are two of these.

The taxic diversity of an area is a measure of the taxonomic dispersion of the species, and the three main concepts are discussed in the previous Chapter (2.1). The simplest measure, *taxic richness*, is like species richness, but counts the higher taxa represented in an area, such as the number of families or phyla. It is on this basis that most coastal systems are markedly richer than the adjacent land area: they contain many more phyla. A traditional measure is to value highly *monotypic taxa*: the ginkgo (*Ginkgo biloba*), the coelacanth (*Latimeria chalumnae*) or the tuatara (*Sphenodon*) are thus valued highly because of their taxonomic or evolutionary isolation (IUCN 1980). A

species in a monotypic order is more isolated on the taxonomic or phylogenetic tree than a monotypic family: this more isolated than a monotypic genus, and so on. Lastly, a recent development has been *phylogenetic diversity* measures which provide a diversity measure of the biota in an area adjusted for the pattern of phylogenetic isolation of the components.

It can be agreed that these measures reflect an evolutionary rather than an ecological perspective. They do, however, approximate to measures of feature richness of importance in valuing areas for conservation (McNeely *et al.* 1990; Faith 1992). The first applications have led to important ideas on conserving complementary rather than overlapping floras and faunas (Faith 1992).

2.3.2.3 Functional diversity

This section discusses two aspects of ecological functionality. The first is concerned with the functioning of species properties for the well-being of the species itself, and is called *autecological diversity*. It treats the species in isolation, that is independently of other species with which it lives. The second aspect of ecological functionality concentrates on the interrelation of species living together. Thus, it concentrates on the different functions a species fulfils relative to other species within a community. In this way, the functions vary between species as well, also adding to the total biodiversity of a region. This aspect of biodiversity can be called *synecological species diversity*, being concerned with the interactions of species living together within communities.

One view of biodiversity in the ecological sense is, therefore, not concerned so much with the species themselves as with their autecological or synecological properties. A reduction in ecological biodiversity involves a loss of types of adaptation, or whole suites of similar adaptive traits. This loss is of a different nature and potentially far more damaging ecologically than a mere reduction in the number of species present.

2.3.2.3.1 Autecological diversity (species in isolation). Each species is unique as regards its present properties, as well as in its often long and complicated evolutionary origin. In a sense, we simply cannot compare them because of their uniqueness; quite literally, we cannot compare apples and pears, nor subtract or multiply them. Biodiversity, emphasizing these differences, is particularly concerned with this biological information, and the measures we use should express it.

An obvious way to treat the variation in one or more traits among species is to arrange species according to the various values or intensities they have relative to a particular trait. Thus, concerning their spreading capacity, they can be arranged from purely sedentary species to those that migrate annually between the two poles, as does the sandwich tern, for example. Then, the numbers of species

falling into various categories along this scale of spreading capacities can be counted. The resulting frequency distribution reflects the profile in this feature, and can be called a *diversity spectrum* (Hengeveld, unpublished data). A reduction in this particular aspect of biodiversity may reflect either a random falling away of species over the whole range of variation of the trait, or a systematic alteration of the spectrum.

Diversity spectra can be constructed for all species on Earth, or locally for those within a particular area. The latter procedure is the more informative, as it can be used to show a loss of adaptive types, but also to track where this loss occurs. Counter-measures should be taken locally as well so as to be most effective in preserving biodiversity.

Diversity spectra can be constructed for many traits, relating either to environmental factors or to the species' demography. Life history statistics come into this category. In botany, they were often known as life forms and the resulting frequency distributions as life form-spectra (Raunkiaer 1934; Fig. 2.3-1). Thus, according to Raunkiaer (1934), the floras of different parts of the world contain species the individuals of which bridge unfavourable periods either in the soil, with their buds just above it, or carrying them high above the soil surface, etc. Locally, the various types occur in certain proportions, together forming a local spectrum. The spectrum could be truncated, for example, by varying the water table affecting particularly those species hibernating as bulbs, or by increasing the turnover of cut forests, affecting the proportion of species with buds high above the ground.

Demographic spectra are known as age distributions, or distance distributions (dispersal kernels), for example. Frequent cropping affects the age distribution, keeping the local population young. This, in turn, affects the reproductive output of the population either positively or negatively. It can be positive when reproductive output is density dependent, the older established individuals with a lower fertility keeping their places. It can be negative, when, with the addition of the offspring of older individuals, the net reproductive rate can reach the minimum value of one for maintaining the population, whereas without it this rate is lower, causing the population to die out sooner or later. High turnover rates of some localities therefore affect different species with different age distributions differently and can thus upset or reduce the local diversity spectrum. This also holds for local dispersal capacities of species. Fragmentation of the environment can leave unaffected the sedentary species for which the remaining fragments are large enough. Very mobile species can also survive as they can still move between the various fragments remaining. However, species with intermediate dispersal capacities may die out as the individual fragments are too small for them to maintain a viable population but covering the

distances between them is impossible. The diversity spectrum splits up into two in this case, implying a loss in biodiversity as such, on top of the loss of a mere number of species.

2.3.2.3.2 Synecological diversity (species in communities). This section discusses the consequences for our concept of biodiversity of the functional living together of sets of species. To this end, however, some other concepts have to be defined and discussed first.

Species can live together without having any interrelationships in groups called *assemblages*. These are therefore aggregations of species that are ecologically independent. When, however, species living together at some locality do relate to each other ecologically, and are interdependent to some degree, we call it a *community*. A community, therefore, is a local set of functionally interdependent species. When, moreover, we also include physical factors and processes in our considerations, the unit is called an *ecosystem* (Tansley 1935). Tansley proposed the term ecosystem to refer to the plants, animals, microorganisms and physical environment at any given place and the complex relationships linking them into a functional system. All units are defined irrespective of the spatial scale of variation with the result that they can be arranged in a hierarchically or nested order. Thus, ponds as individual ecosystems can be connected by streams into a system comprising a large catchment area. This large area therefore is considered a spatially broad-scale ecosystem. This also applies to communities. Assemblages are similarly defined without reference to particular spatial scales, but these cannot meaningfully be defined in a hierarchical or nested order.

Internally, communities can be structured according to the functions of species. First, each species occupies what is called an ecological niche, which may be depicted in terms of the range of ecological conditions that the species occupies and its functional position within the community (Colwell 1992; Griesemer 1992). Niche space is complex and multidimensional (Hutchinson 1959), and in practice it has been characterized in terms of ranges of such variables as temperature, moisture, light, salinity, acidity, depth; position within the physical structure of the habitat (resting substrate, feeding location); diurnal versus nocturnal activity; defences against enemies (adaptations for escape, hiding, or crypsis); attributes of food items and feeding substrates (size, noxious chemicals, taxonomic group); feeding behaviour (ambush, search, filter, etc.); and many other factors. Niches that are characterized irrespective of the species' functional role in the community remain unweighted.

When several species have similar niches, and also similar functions, they form functional categories called *guilds* (Root 1967; Jaksic 1981). Guilds may reflect discrete groupings (Jaksic and Medel 1990) or arbitrary but

useful subdivisions of a continuum (Simberloff and Dayan 1991). An approach that has proved successful in animal communities is to calculate the variation among taxa in morphological measurements related to functional aspects such as feeding, predator escape, and other attributes of the niche space (Karr and James 1975). Statistical methods for treating such data involve multivariate analyses, ordination, canonical correlation and discriminant analysis (Gaugh 1982; Miles and Ricklefs 1984; ter Braak 1986). Such analyses permit rapid comparisons of ecological variety among assemblages, such as for the bird faunas of island archipelagos and continental areas, but they are limited to taxa with comparable structures (that is, birds and ants cannot be included in the same analysis even though they may consume some of the same resources).

Communities can also be characterized by means of specific connections between species. One of the simplest functional characterizations is based on how organisms obtain their nutrition. Organisms that obtain their food by the same number of steps from plants are said to belong to the same *trophic level*. By using the feeding relationships of organisms the community can be broken down into a few easily recognizable groups, such as producers, decomposers, herbivores and carnivores.

The flow of energy from plants through herbivores to carnivores is termed the *food chain*. Food chains are not independent but interlinked to form *food webs* (Pimm 1982) which can be quantified by the number of trophic levels, number of links (that is, predator and prey species) per taxon, and so on (Cohen *et al.* 1990; Polis 1991; Martinez 1992; Hall and Raffaelli 1993). Paine (1992) has additionally developed an experimental approach that defines functional food webs by measuring the strength of interactions between populations.

At each transition, from one level to the next, energy and nutrients are lost. This often results in a decreasing number of species from the base towards the top, producing a characteristic trophic pyramid (Elton 1927). The structure of the trophic pyramid relates directly to the functioning and organization of a community, and changes in ecosystem function due to, for example, nutrient enrichment (Palmer *et al.* 1992) or pollution can be detected in changes in the trophic structure. The structure of food webs can also provide indications of community organization and persistence. Some webs remain stable with the addition or removal of additional species whilst others become unstable and result in further losses (Pimm 1982).

Within a community a species may have a functional role that is critical to the stability and survival of the community. Such species are termed *keystone species* (Paine 1966). The loss of a keystone species will result in widespread changes in community structure and often result in further species loss. This concept is discussed fully in Section 5.2.3.

2.3.3 Diversity between areas

2.3.3.1 The general difficulties in classifying ecological communities

Each species has a unique distribution, which is the product of its ecological and evolutionary history. It follows that no two areas are identical, and that there is a potentially infinite variety of ecological associations. We can of course see strong patterns in communities, which often reflect important differences in environmental conditions, but the apparently straightforward task of classifying this variation proves to be extremely complex. In this section we consider some of the theoretical issues associated with attempting an ecological classification. Then we go on to take a pragmatic approach to how these problems may be overcome, in order to produce effective working classifications. The latter permit us to obtain some measure of ecological diversity between areas. These are the issues.

1. There is nothing equivalent to the species concept that can provide a fundamental criterion for defining ecological units. This simple but important conclusion has had profound implications for ecology. One of the false directions taken by some early ecologists was in regarding ecological associations as having some reality, rather than as abstractions that are useful for practical purposes. Thus, Clements (1916) regarded an association as a complex organism, and this type of thinking had a profound effect on development of ecology. The contrasting philosophy was that of Gleason (1926) who proposed the individualistic concept of the plant association, which basically relates the continuously variable environment to equally continuous variation in ecological communities. Most ecologists nowadays would regard this interpretation as more realistic.
2. It follows from (1) that there is no single form of classification which we can regard as natural and which provides the ideal towards which we aim. Classifications based on very different criteria (for example floristic species composition, faunal species composition, ecosystem properties, etc.) are all equally justifiable; we should not expect that classifications based on different criteria will correspond (Hengeveld 1990).
3. The boundaries drawn between ecological units are necessarily arbitrary. In some areas environmental uniformity leads to a uniformity in the structure and composition of naturally occurring communities. However, in other areas species composition will change, sometimes markedly along environmental gradients. Such areas of transition are termed ecotones, and the decision as to whether to regard them as a

distinct type of community or merely intermediates between distinct communities is entirely arbitrary.

4. The natural patterns of variation in species composition present serious problems of scale. The different units that we may define vary in spatial extent and no simple sampling scheme can capture all the variation. A coarse classification, one for example that recognizes a distinct unit of beech woodland in Europe, completely fails to capture the great richness of variation in ecological associations which occur within this type of community. A particular problem in attempting to inventory ecological diversity is presented by very small ecological units, which may be quite distinct and in no sense part of the matrix of communities in which they occur. Examples include ecological communities associated with isolated rocks, with springs, ponds, etc. These small units may have many unique species, but a large scale classification provides no indication of their possible presence.
5. A related problem of scale is that the data that can be used for classification at one scale may be unavailable or inappropriate at another scale. For example within a protected area of rain forest, it may be useful to classify the vegetation according to species composition. However, at a much larger scale, such classification would be impossible because the data needed could not be collected. Large-scale surveys would have to be based upon some other characteristic of the vegetation than species composition, for example structural (physiognomic) features of the vegetation. At a global scale we are often more interested in the structure and functioning of an ecological system than in its composition. Tropical rain forests in different continents differ almost completely in species composition, but it is useful to recognize these different communities of species as all belonging to the same type of ecosystem.

Faced with these theoretical and practical problems of classifying ecological communities, it is not surprising that there is no generally accepted form of ecological classification. Instead there is a bewildering range of different systems of classifying communities, some of which are widely used and some of which have been developed for just one purpose. As a broad generalization, diversity of ecological systems is usually assessed at one of two levels. For large-scale purposes, ecological classifications are based on the types of ecosystem, with main attention paid to structure and organization of the community rather than species composition. On a local or regional basis, such classifications are often replaced by classifications based on the species present. For practical purposes, both types are usually derived from information about the vegetation rather than the fauna.

Figure 2.3-3: (a) Main faunal provinces of African freshwater fish (from Greenwood 1983), and (b) main phytochoria of Africa (from White 1983).

Figure 2.3-4: Distribution of tropical forest and representative climatic conditions. Mean monthly temperatures are indicated by the line and mean precipitation for each month is shown by the bars (from Archibold 1995).

2.3.3.2 Classifications based on species composition

2.3.3.2.1 Phytosociology. The aim of phytosociology is a world-wide classification of plant communities, using the presence and abundance of plant species as a basis for classifying and characterizing vegetation.

On the European continent phytosociology has been extremely popular, and for many decades the approach dominated European plant ecology to the near exclusion of other approaches. The longest-established and best-known tradition in phytosociology is the so-called Zurich–Montpellier school (Grabherr and Kojima 1993). The method focuses on analysis and synthesis of floristic lists collected from relevés or stands which represent a sample of a type of vegetation. Herein lies one of the objections to this approach, since the selection on the relevé is not random, but based upon the observer's experience of the vegetation and judgement as to whether it is typical. Relevés are grouped and classified according to floristic similarities, based not only on dominant

species but also on the entire assemblage. A group of relevés which possess some species in common, and which are not found to occur in other groups, is considered to be one type of vegetation. The basic unit of classification is the association, and these are grouped into higher categories analogous to the taxonomic ranking of species into genera, families, orders and classes. Thus in the Zurich–Montpellier school of phytosociology associations are grouped into alliances, orders and classes.

Although there is nothing approaching a comprehensive global vegetation system based on floristic criteria, the phytosociological approach has been applied very widely, particularly in Europe. For some types of vegetation (for example mire and alpine steppe vegetation) there are fairly complete phytosociological descriptions of the vegetation, at least in the Northern Hemisphere.

Phytosociology has attracted a great deal of criticism, particularly from the Anglo-American school of ecology. The objections include the subjective selection of 'typical'

Figure 2.3-5: Global classification systems.

sites, the subjective identification of associations (though modern quantative methods have reduced the force of this objection), and the arbitrary hierarchical classification of associations. However, despite these objections, phytosociology is practically useful. In those countries where it has been practised intensively there is a very full knowledge of the range of types of plant community and this information is increasingly important in conservation planning, resource management and monitoring of environmental change. Although based on floristic data, the classifications are also useful in predicting the distribution and richness of associated fauna.

Outside continental Europe, phytosociology has attracted less interest and as a result much less is known about the types of vegetation. For example, in Britain in the 1970s there was no comprehensive classification of British vegetation types which could be used as a basis for formulating conservation priorities. In this case, the solution was to commission a major survey known as the National Vegetation Classification (NVC) (Rodwell 1993). This was based on the phytosociological approach, but sought to avoid those aspects of the European tradition that were regarded as unsatisfactory. Thus although the NVC approach was based on systematic recording of floristic information from stands of vegetation, these were chosen solely on the basis of their relative homogeneity in composition and structure. No prior judgements were made

about the identity of the vegetation type; nor were sites selected because of the presence of species thought characteristic for one reason or another. The classification also employed reputable methods of statistical analysis, and in particular the classification technique known as TWINSPLAN.

2.3.3.2.2 *Global classifications of species distribution.* At a large scale, species information can be used to determine global patterns of diversity. For example, direct comparison of the species composition of the flora and fauna in different parts of the world can be used to identify distinct *biogeographic* areas (*phytogeographic* – flora, *zoogeographic* – fauna). These have traditionally been distinguished by high levels of endemism in their component species, with regions classified by the presence or absence of particular taxa. Recent techniques, however, tend to use characteristic combinations of taxa, and use statistical procedures such as cluster analysis and ordination techniques to compare the similarity/dissimilarity of the species composition of areas (Hengeveld 1990).

At the largest scale, *biogeographic regions* are identified (Figure 2.3-2). Boundaries between biogeographic regions or provinces are called *biogeographic lines*, the most famous of which is Wallace’s Line between Southeast Asia and Australasia. In a classic study, Wallace (1879) noticed that the similarity of species in the Old World tropics was

Figure 2.3-6: Distribution of the major terrestrial biomes of the world From (Cox and Moore 1993).

Figure 2.3-7: Holdridge's life zones (after Holdridge 1967).

Figure 2.3-8: The world's ecoregions (after Bailey and Hogg 1986).

Figure 2.3-9: The world's biogeographic realms and provinces (after Udvardy 1975).

Figure 2.3-10: Oceanic realms (after Hayden *et al.* 1984).

high when comparing areas on one side of a hypothetical boundary but very low when comparing areas across that boundary. That boundary we now call Wallace’s line and it divides species that evolved to the north (the Oriental Region) from those that evolved to the south (the Australian Region). Whatever its causes, Wallace’s Line separates two very large regions by marking a boundary of high between-area diversity. Boundaries, however, are rarely as clear-cut as Wallace’s Line, and often are vague and consist of broad transition zones, with component taxa declining gradually from their centre and merging into surrounding units. Furthermore, while the boundaries of the largest biogeographical regions tend to hold true for many groups, at the smaller, regional scale the boundaries are often taxon-specific: for example, the floristic regions of Africa differ from those of freshwater fish (Figure 2.3-3). Boundaries are also often dependent on the taxonomic level that is used: for example in a study of echinoderms around the Isthmus of Panama, the distribution of genera was found to be different from that of species (Raup and Crick 1979).

Zoogeographic regions have also been identified in the marine environment (Briggs 1974). However, the marine environment is more complex and dynamic than the terrestrial environment, and there are no universally agreed classification systems. The marine environment is three-

dimensional with distinct vertical zonation and endemism (Vinogradova 1962): for example, some genera and families are found only at oceanic depths over 3000 m. Within a particular ocean basin, the distributions of intertidal species, species of the upper layer of the open ocean, and deep sea species are very different (Norse 1993).

2.3.3.3 Global classifications of ecosystems

Ecosystems are essentially dimensionless, and the boundaries of the system in question can be defined according to the convenience of the researcher. Because the ecosystem approach to ecology is concerned with processes, such as the flow of nutrients and energy, much less emphasis is placed on species composition. We can recognize ecosystems that are physiognomically the same (that is in terms of their structure) and which function in much the same way, even though in terms of species they are different. Thus tropical rain forests in South America, Africa and Asia are clearly all the same type of ecosystem (Figure 2.3-4). Indeed, one the great advantages of the ecosystem approach is that very different ecosystems, with totally different species compositions, can be compared.

At a large scale, variation in ecosystem structure is closely related to controlling environmental variables and particularly the climate. Approaches to ecosystem classification therefore use a wide range of parameters,

including aspects of the structure or physiognomy of the vegetation, as well as of climatic conditions (Figure 2.3-5). Because there is no need to identify particular species, it is also possible to make inferences about ecosystem type on the basis of remote sensing information. Indeed, it is increasingly recognized that the most versatile approach to ecosystem classification is to use satellite imagery for data on structure and phenology.

The link between vegetation and climate was recognized in the earliest attempts to classify world vegetation. De Candolle (1874) proposed that the distribution of the major plant formations was related to their drought and heat tolerances, and Koppen (1884) used annual and monthly rainfall and temperature to identify five major climatic zones which were intended to correspond to the major vegetation zones. These early approaches led to the development of more formalized classification techniques, which classify the terrestrial environment according to the structure and function of naturally occurring communities. The problem has been approached from two angles. The first has been to classify systems according to the physical structure of the dominant vegetation type, and such an approach is termed *physiognomy*. The alternative approach has been to use environmental variables to describe the *abiotic template* on which the distinctive communities are found.

The largest ecological unit recognized by physiognomy is the *biome* (flora and fauna) or *formation* (flora only), of which the tropical forests illustrated in Figure 2.2-4 are an example. Other biomes include the tundra, boreal forest and the savannah (Figure 2.3-6). Physiognomy is used predominantly in terrestrial systems. In freshwater and marine environments the vegetation has neither the structural diversity nor the regional uniformity to enable such classifications to be made.

Some more recent classification systems which describe the terrestrial abiotic environment have also been based on climatic variables. Holdridge (1947, 1967) devised a Life Zone Classification (Figure 2.3-7), which uses climatic variables to predict the naturally occurring climax community. This system has been incorporated recently into models of global change. A restriction of this system was that each locality was assigned only one unique ecosystem type. Box (1981) extended this system to a more complex concept related to species growth forms and the possibility of their coexistence. He found that using climatic data he could predict with a high degree of accuracy the mix of plant growth forms and the dominant types that would occur in a locality.

Climate, however, is only one component of the abiotic environment, and can be used only to predict the potential ecosystem type. While this may be of theoretical interest, there is an increasing need – for purposes such as climatic modelling and resource management – for classification

systems that take account of other factors such as soil conditions and land use. Such schemes tend to use a more or less elaborate combination of variables including habitat type, climate, land use, etc. For example, Bailey and Hogg (1986) incorporated aspects of the physical environment into a classification system to delimit a series of global ecoregions (Figure 2.3-8). This system uses a detailed bioclimatic classification and several features of the landscape, such as landform (soil type, drainage patterns) and altitude to describe a physical template on which similar communities would develop. By increasing the number of variables used to describe areas more detailed regional classifications can be constructed (Bailey 1989). The Bailey Classification includes four domains, further subdivided into 30 divisions and 96 provinces, and is intended to demarcate ecologically similar areas in order to predict the effects of management or global change. The EC CORINE Biotopes System is conceptually similar, but focused at present at the European level: it is founded on detailed data from a large number of sites.

Olson *et al.* (1983, 1985) developed a global ecosystem map based on data about pre-agricultural and potential vegetation, on contemporary land survey, and biomass data from research sites. They defined seven broad groups subdivided into a mosaic of 44 ecosystem units resolved at the level of a $0.5^\circ \times 0.5^\circ$ grid. Even at this relatively fine resolution, one grid cell at the Equator will include 3 000 km² (equivalent to a square of about 55 km \times 55 km), which will limit applications at the national level. One value of this particular system is the attempt to deal with transitional and disturbed systems. A primary reason for development of the Olson *et al.* data set was to enhance research into carbon storage and the global carbon cycle. The vegetation data were used by Prentice *et al.* (1992) as elements in their global biome model.

A system that combines the physiognomic and biogeographic approaches to the characterization of global biodiversity is the *Biogeographical Realms and Provinces* of Udvardy (1975). In this system the structure of the climax community is the first step in identifying a biogeographical province: however, the presence of distinctive flora and fauna is then used to delineate boundaries (Figure 2.3-9). The system covers terrestrial systems only, and divides these into eight biogeographical realms which are further divided into 193 provinces. The system has been widely used, by IUCN for example, as a basis for assessing the representativeness of global protected areas. A similar integrated approach has been adopted for marine environments (Hayden *et al.* 1984; Figure 2.3-10), combining the geophysical template based on variables such as salinity, surface currents and temperature (from Dietrich 1993), and the zoogeographic realms of Briggs (1974), to produce a global classification of the marine environment. Another system has described 49 large

marine ecosystems (LMEs) encompassing coastal areas from river basins and estuaries out to the continental shelf or the seaward margins of the coastal current systems (Sherman 1994). Ninety-five per cent of the annual biomass yields of fish and other marine resource are produced in these LMEs.

The characterization of global biodiversity patterns using environmental variables relies on the assumption that environmental uniformity will lead to uniformity in the structure and function of the community that develops. This is valid for naturally occurring climax vegetation (such as tropical forests; Figure 2.3-4), but the relevance of such classifications for animals is less clear. The most obvious examples of functional convergence amongst animals come from the Australian fauna, where the functional equivalents of eutherians can be identified amongst marsupials. Cody (1974, 1975) demonstrated that sets of insectivorous birds exploiting the Mediterranean vegetation of the Californian *chaparral*, Chilean *matorral* and South African *macchia* showed morphological convergence in their adaptations to apparently parallel niches. Such conformity in community structure has also been indicated in montane lizards in Chile and California (Fuentes 1976) and finches (Schluter 1986). However, other workers have failed to identify such fixity of community design (Lawton 1982), and the generality of the relationship amongst animal communities is open to question (Lawton *et al.* 1994; Putman 1994). Such systems are also less relevant in areas dominated by anthropogenic environments.

2.3.3.4 Characterizing and classifying landscapes

At a local or regional scale, more detailed ecological classifications are usually required than those provided by global systems. To some extent, the ecosystem units described above (2.3.3.3) can be broken down into smaller units to produce a hierarchical classification. For example, biomes are subdivided into associations, biogeographic realms into provinces, etc. This is achieved by the addition of new variables to the classification. For example, Klijn and Udo de Haes (1994) demonstrated how the use of additional environmental variables could increase the resolution of an ecosystem classification in the Netherlands.

At this regional scale (10–100 km) *landscapes* are identified. The increased detail required by landscape classifications means that there are no globally accepted terms or definitions, and one can provide only regional examples (Bailey 1981; Orians 1993; Klijn and Udo de Haes 1994). Opportunities for large-scale comparisons are therefore limited. In Britain, for example, four main classes of landscape are commonly recognised: *uplands*, *marginal uplands*, *pastoral* and *arable* (Stott *et al.* 1993). Within the 'upland' landscape division, the Countryside Survey has five lesser categories (managed grasslands, rough grasslands, heaths and bogs, broad-leaved woodlands and coniferous

woodland). Not surprisingly, an entirely different classification is needed in Mexico. Miranda and Hernandez (1963) recognize different zones, of which say *selva alta perennifolia* is a statement of the likelihood that the plant species found there will typically be found in many places in this zone and typically be different from those in other zones.

The functional importance of studying biodiversity at the level of the ecosystem or landscape is discussed in Sections 3.5 and 6.2.4.

2.3.3.5 Diversity in ecological systems

Although we have seen a wide diversity of approaches to classifying ecological systems, in each case the aim is to map every point in space in terms of a limited set of classes. However, another aspect of biodiversity is the *range* of ecological systems that occur within an area. For example, a landscape is usually a mosaic of different elements such as forest, agricultural land, wetland and so on. Once we have identified the basic types of ecological unit within a region, whether at the biome, landscape or habitat scale, we can make descriptive comparisons between different areas on the basis of the number of ecological systems they contain. For example a mountain range, due to the effects of altitudinal zonation, would contain a greater number of biomes than a tropical rain forest, although the number of species contained in the rain forest may be greater. To permit such comparisons accurate classifications of the systems are essential (Box 2.3-2).

Another important aspect of the diversity of the systems may be their spatial arrangement. For example, the way the various elements that make up a landscape are arranged in space is itself an aspect of diversity and may be important in determining which species can live in an area. Particular species may require patches of a certain habitat about a certain size, or they may require a particular mix of habitats. Thus the range and absolute areas of each habitat within an area provide an imperfect description of the ecological diversity. We may also need to consider various aspects of the arrangement of these habitats and the heterogeneity of the landscape they produce. These spatial aspects are difficult to describe, but is increasingly recognized that landscape analysis of this type is important in understanding species diversity.

2.3.3.6 The importance of better ecological classifications

This brief review of approaches to describing ecological diversity has done little more than illustrate the diversity of approaches and the complexity of the issues. There can be no single classification of ecological systems, since they are highly multivariate. The diversity of approaches reflects both the different objectives of different classifications, and also theoretical differences about the nature and organization of ecosystems. There are strong tensions

Box 2.3-2: Comparing the diversity of systems – classification prior to comparison.

The analytical procedures developed for the Countryside Survey of Great Britain (Barr *et al.* 1993) have been developed into a formalized procedure using the principle of classification prior to comparison.

Biodiversity is compared only between classes of vegetation that are relatively homogenous, in order that changes in species number and composition are not confounded by comparing vegetation classes that are inherently different. For example, a significant reduction in species number could be recorded in systems of low diversity such as cropland due to the loss of only one or two species. By contrast, a loss of far more species could occur in a high-diversity system such as unimproved grassland before a significant reduction was detected.

It is therefore necessary in observing ecological change to consider the inherent within-area diversity of the systems. Whilst in an ideal situation these classes would be determined by objective procedures, usually these will be determined by expert judgement.

When considering the three main levels of vegetational classification (biomes, landscapes, associations) it is fundamental that collections of associations combine to form landscapes, which in turn combine to form biomes. For example, within the Lusitanian biome there will be coastal, lowland, mountain valley and montane landscapes. Within each of those landscapes there will be different associations, for example the biotopes as defined by the EC CORINE system. Thus the montane landscapes will contain associations of alpine species, grasslands, heaths, scrub and forests.

A similar procedure involving a variety of measures including biodiversity is being proposed for the preparation of a Red Data Book for threatened landscapes by the CESP commission of IUCN. The principle is that a variety of measures are used to compare different landscapes within the same class.

patterns: in natural communities the boundaries are often more vague.

Multivariate statistical techniques (Jones and Bunce 1985) are increasingly important in providing the method for classification and work well for some data sets (such as, for example, species composition). However, much classification, for example of landscapes and biomes, is based on judgement and experience rather than on objective methods. The subjectivity does not necessarily diminish the utility of the result. A historical example makes the point. C.H. Merriam worked in Arizona, USA in the 1880s. He characterized the biodiversity into seven 'life zones' on the basis of the appearance of the vegetation. Providing maps and elevational transects, he mapped these zones across the northern part of the state. Merriam's classification preceded formal vegetational surveys and the array of sophisticated computer-intensive statistical analyses now available. None the less, a century later his classification retains its utility as a broad guide to where species of plants and animals will be found and where the boundaries between their distributions lie. Similarly, despite all the criticisms of phytosociology, the method has provided a practically useful inventory of the types of vegetation in many areas.

All of the existing global classifications of ecological systems are to some extent inadequate, either in their methodology or in their spatial coverage, or in both. We urgently need a robust classification of the world's ecosystems which can be used to map the distribution of ecological resources. This need is partly to provide a basis for assessing biological diversity and for setting priorities for conservation, and also for many other purposes associated with environmental change. The urgency and magnitude of this task means that compromises must be found between theoretical rigour and practical feasibility. The task will inevitably require information of many kinds including remote sensed data, field assessment, and documentary information.

2.3.4 Conclusions

1. Organisms are not evenly distributed: they occur in an intricate spatial mosaic, classified on a world scale into *biogeographic zones*, *biomes*, *ecoregions* and *oceanic realms*, and at a variety of smaller scales within *landscapes* into *ecosystems*, *communities* and *assemblages*.
2. In terrestrial systems the community found at any one point can be characterized by the physical environment (ecoregion), the physiognomic type (biome), and the floristic/faunistic (biogeographic) zone in which it occurs. In marine systems communities are characterized in terms

between the theoretician and the practitioner. The theoretician seeks an objective basis for classifying ecosystems, and rigorous methods both for sampling ecological systems and for establishing the distinct units.

How does one recognize a biome, landscape, habitat, or biotype? Certainly, when sufficient data are available, there are formal statistical procedures that group smaller areas into larger divisions according to the principle that the diversity is low within and higher between those divisions (Hengeveld 1990). In anthropogenic landscapes boundaries are often easily identified as simple differences in land-use

of the physical environment and the faunistic (biogeographic) zone.

3. The units of classification used on a global scale differ in how they are recognized and consequently in the distinctions between their subdivisions. Biogeographic zones differ taxonomically in the flora and fauna present, even between areas of similar physical environment (e.g. within the same ecoregion) or similar physiognomy (e.g. within the same biome). Conversely, the physiognomic differences between biomes within one biogeographic zone are paralleled by those within another.
4. The biodiversity within an area can be characterized by measures of *species richness*, *species diversity*, *taxic diversity* and *functional diversity* – each highlighting different perspectives.
 - (a) Species richness (also called α -diversity) measures the number of species within an area, giving equal weight to each species.
 - (b) Species diversity measures the species in an area adjusting for both sampling effects and species abundance.
 - (c) Taxic diversity measures the taxonomic dispersion of species, thus emphasizing evolutionarily isolated species that contribute highly to the assemblage of features or options.
 - (d) Functional diversity assesses the richness of functional features and interrelations in an area, identifying *food webs* along with *keystone species* and *guilds*, characterized by a variety of measures, strategies and spectra.
5. At the smaller scale landscapes are composed of areas characterized as ecosystems or communities. The diversity between areas is measured as β -diversity, the change in species present.
6. *Systems diversity* is assessed as the richness of ecological systems in a region or landscape.

EXECUTIVE SUMMARY

The current magnitude of biodiversity

- An understanding of the magnitude of biodiversity at all levels is crucial to its conservation, management and utilization. The scale of biodiversity is immense, and while estimates of its magnitude are being improved, investment is required to bridge crucial knowledge gaps and synthesize existing information.
- The magnitude of biodiversity can be examined at scales ranging from the ecosystem and habitat, through the organismal, down to the genetic levels, including domesticated diversity.
- Ecosystem classifications are largely based on vegetation, but need to take into account changes brought about by humans, and also climatic and biogeographic variables.
- Systems designed for use at the global level are of limited value at scales important for conservation purposes.
- As total site inventories are not available, ecological classifications are an important component in the assessment of sites for conservation purposes.
- Organismal biodiversity can be assessed at different levels of the classification hierarchy from kingdoms and phyla, through orders, families, genera, and species, right down to the infraspecific and genetic levels.
- Different uses of the category 'species', and the importance of phylogenetic divergence, mean that organism diversity cannot be measured objectively solely by differences in species number: the 'species', although the most commonly used unit of biodiversity, is not a standard unit of biodiversity measurement.
- The working figure of 1.75 million species is the current best estimate for the number of living (non-fossil) species currently known to science.

- An estimated 90% of the described species have never been included in regional accounts of biotas, or in identification manuals or modern monographs.
- The described species represent only a small proportion of species on Earth, and a working estimate of 13.6 million is adopted here as the overall total that exists; this suggests that only 13% of the species on Earth have yet been described.
- Molecular and genetic studies demonstrate that there is enormous diversity at the infraspecific level in almost every species examined.
- A high amount of genetic variability is found in most species. For animals, variability is on average greater within invertebrate than vertebrate species, which have more subdivided populations. For molluscs, amphibians, reptiles and mammals, about 25–30% of this variation is due to genetic difference between populations, whereas for birds and insects, which have higher gene flow between populations, this figure is only 8–10%.
- In plant species, there is a wider range of variability between different species. Breeding system is the main determinant of the pattern of genetic variability in plants.
- An indication of the extent of genetic diversity present within a species can be obtained from domesticated organisms; for example, seven separate vegetables are derived from the single species *Brassica oleracea*, and more than 800 breeds of sheep derive from *Ovis aries*.

The distribution of biodiversity

- Diversity and its distribution are the product of a long history of evolution, diversification and extinction in a complex and changing geographical/ecological setting.
- Patterns of biodiversity are the product of evolutionary diversification interacting with local ecological processes, which are influenced by the

intrinsic characteristics of organisms, and how the landscape and seascape are structured. The maintenance of diversity in natural and managed ecosystems depends upon our understanding of these local processes, while setting up regional conservation priorities must be underpinned by an understanding of the mechanisms that produce diversity and allow it to accumulate over evolutionary time.

- Within regions, certain features such as habitat productivity, structural complexity and topographic heterogeneity allow prediction of diversity *per se*, but not phylogenetic uniqueness, which may be associated with habitat uniqueness or stress, and historical accident.
- Long-term prospects for biodiversity are completely altered by changes in geographical distributions, at all scales, of biotas and their member species.
- Local diversity is maintained over ecological time periods by landscape-scale processes.
- Most studies on distribution have concentrated on macro-organisms, and in the case of fungi and other microorganisms in particular, the current level of ignorance precludes generalizations on distribution.
- Endemic taxa may be restricted to certain sites, biotopes, regions, political areas, map units or an arbitrary upper limit for range size. Endemics play a major role in reserve selection, based primarily on the complementarity of endemic taxa.
- Although major centres of endemism have been detected, more work is needed to refine centres with regard to the phylogenetic uniqueness of species and their relative range sizes. Detection of further centres of endemism requires increased survey work.
- Basic biodiversity inventory work is crucial to a clearer understanding of what species are endemic to which region.
- In many groups of organisms, endemism is most pronounced in the tropics and south-temperate areas. It is largely a function of historical factors, but these interact strongly with others such as environmental heterogeneity, taxon mobility and degree of isolation.
- Endemics are often highly vulnerable to anthropogenic disturbance and other forms of environmental change, and are often indicators of biodiversity-rich locations. Detailed phylogenetic analyses and geographic distributions of a small number of groups may facilitate our understanding of the development of particular biotas.

Endemism and biodiversity

- Endemism is a term applied to taxa that are restricted to a particular geographical area or ecological unit: definitions are tailored to particular needs. Endemism therefore signifies unique biodiversity.
 - There is a need to identify centres of endemism using rigorous methods, and to develop predictive models of the abiotic and biotic correlates of endemism. Data suitable for testing hypotheses of community convergence and ecological saturation are almost wholly lacking.
-

3.0 Introduction

The objective of this Section is to examine what is known of the magnitude of biodiversity and its distribution in ecological, organismal, and genetic terms (see Section 1.2.0). An assessment of the current magnitude of biodiversity (Section 3.1) is fundamental to all discussion about its conservation or sustainable use, and here it is vital to distinguish truly informative data from those which provide an inadequate or inappropriate basis for extrapolation. The extent and location of the resource base required for biodiversity assessments is a key aspect in the refining of estimates at all levels, and it is therefore given special attention elsewhere (see Section 8)

Section 3.2 considers the distribution of biodiversity, the identification of centres of diversity and endemism, and their relevance to the selection and prioritization of sites for conservation purposes. Endemism often assumes a high profile in discussions of conservation priorities, but the use of the concept and its evaluation require careful scrutiny (Section 3.3).

3.1 The current magnitude of biodiversity

3.1.0 Introduction

For many aspects of biodiversity there are no generally accepted ways of characterizing or quantifying the constituent elements. For others, the task is straightforward enough but can only be performed within a given context or at a given scale, and the information cannot simply be summed to give an assessment of the magnitude of this aspect of biodiversity in a broader context or at a larger scale. For yet others, although a summing of data is feasible, the results obtained may have little scientific or practical significance. For most aspects of biodiversity the questions of how 'special' a given definable unit is (e.g. see Section 2.1.6), as well as how rich or diverse it is will be of interest, and in many instances the former is of paramount significance. For these reasons, this section focuses primarily on taxonomic units, and on species in particular, not because these are of greater significance in biodiversity terms than ecological systems or genes but because these taxonomic units can be counted and, if identified securely, summed across ecological hierarchies and across geographical scales.

3.1.1 Ecosystems and habitats

As already noted, it is now customary to consider biodiversity in ecological, organismal (taxonomic) and genetic terms, and at a variety of levels for each of these (Box 1.2-1; and see May (1994a, b) and Section 1.2.0 for a fuller discussion). The key units in the ecological hierarchy, as in the taxonomic hierarchy, are populations, rather than the individuals of which they are composed or the species to which the populations belong. However, in

practice species provide the main point of reference in most attempts to quantify and assess the magnitude of ecological systems at other levels (see Sections 2.3.2, 2.3.3), as well as occupying a central role in biodiversity studies in general (3.1.2.1).

Both genes and species can be regarded, simplistically, as identifiable units that define themselves through replication or reproduction. The ecological systems in which genes and species are found, such as habitats and ecosystems, have no such identity: they are more conceptual entities than genes or species; they do not exist as discrete units, but represent different parts of a highly variable natural continuum; they interdigitate and intergrade in complex ways, the perception of which is heavily scale-dependent; they change through processes of succession and degradation; and they do not perpetuate themselves, but are kept in existence or recreated by the species of which they are comprised and the abiotic factors that affect them.

Thus, while terms such as biome, ecosystem, biocoenosis, habitat and community are widely used, their classification, their precise delimitation, and any assessment of their global diversity are beset with difficulties. These difficulties are compounded by issues of scale, and by biotic differences between continents. There is no internationally accepted standard classification of ecosystems and related phenomena for global application; although there are many options, depending on the purpose to which the classification is to be put, and the scale at which it is to be used. Some of these options are discussed in Section 2.3.3. Questions about the global magnitude of ecosystem or habitat diversity will receive as many answers as there are systems for classifying the phenomena whose diversity is being assessed. In fact, any such global assessment may be open to challenge on theoretical grounds. The key issues are related: to what extent can the natural world be described as a mosaic as well as the continuum that observation suggests; and if at progressively larger scales each part of the world is seen increasingly to be unique, at what scale are spatial generalizations valid?

Geographic boundaries between ecosystems (or units of other types) will be easier to draw the more fully their contents can be defined, for example in terms of structure and species composition, but the system of classification used will at the same time thereby become more site-specific and therefore less useful for global analysis. However, the use of satellite imagery to furnish data on vegetation structure and phenology, in conjunction with a Geographical Information System (GIS) has introduced a new versatility (UNEP/GEMS 1993). In a GIS the satellite data can be managed with minimum classification; different factors can be represented in different GIS layers, and can be aggregated as appropriate to the scope of the task in hand (see Section 7.2.10).

In practice, ecosystem diversity has been assessed most usefully at two principal levels: first, at a very generalized global level (see Section 2.3.3.3), with emphasis on climatic determinants of ecosystem type; secondly, on a local or regional basis, and largely in terms of vegetation or diversity of species present (see Section 2.3.3.2).

3.1.1.1 Ecosystem diversity

The term ecosystem, as noted earlier (see Section 2.3.3), is in a sense non-dimensional and its boundaries are defined according to the convenience of the researcher. In its original usage, therefore, ecosystem diversity could be assessed primarily on a local basis, and in terms of diversity among some set of system components (e.g. the number of trophic levels or the biomass of primary producers). But if explicit reference to ecosystem dynamics is omitted, the concept of diversity within ecosystems becomes closely equivalent to species diversity. Also, statements about ecosystem and habitat diversity, or trends therein, often use the terms ecosystem and habitat more or less interchangeably, and tend to converge on what, in practice, is a statement about elements of landscape.

3.1.1.2 Habitat diversity

A **habitat** may be defined as the space used by an organism, together with the other organisms with which it co-exists, and the landscape and climate elements that affect it. The terms in which a species' habitat may be defined will differ greatly at different scales and for different kinds of organism (consider a bacterium, a badger and a blue whale). Habitat change that one species might find intolerable could be imperceptible to another, and beneficial to a third. Habitat diversity, narrowly applied, should refer to diversity in the habitat of some given species: loosely applied, it tends to refer to gross structural or compositional differences in the local environment of some community of species. However, if in any given landscape there are as many habitat dimensions as there are species present, general statements about global habitat diversity or about the status of habitats can have little meaning without specific reference to those living entities for which some given place is a habitat.

3.1.1.3 Assessment of global ecosystem diversity

For use at the global level, there is no universally accepted classification of ecological systems (see Section 2.3.3). Many classifications, however, are based on vegetation type. Robust but necessarily simplified schemes of this type have been adopted for the purpose of modelling global climate change. These tend to use a more or less elaborate combination of a general definition of habitat type with a climatic descriptor (e.g. 'tropical moist forest'). Some also take into account the effects of human activity and/or

incorporate a biogeographical element (see Section 2.3.3.3).

To the extent that their units of classification can be equated with ecosystems (*sensu lato*) classifications of such as those of Bailey, Udvardy and Holdridge (see Section 2.3.3.3) can yield a general view of the global diversity of kinds of ecosystem. However, precisely because of their global focus, they are able to furnish relatively little information about comparative diversity within and between ecosystems or habitats, and little that is applicable to site or national planning issues (this was rarely or never the original purpose).

3.1.1.4 Assessment of local biological diversity

This incorporates two related issues. The first concerns the intrinsic diversity of an area; an area with higher diversity may be deemed more important than one with lower diversity. The second concerns assessment of the contribution any given area makes to the overall diversity of a larger geographic region, such as a country, continent or, ultimately, the world overall. From this perspective, some areas with lower intrinsic diversity may be more important than others with higher diversity.

Biological diversity measures for particular areas, habitats or ecosystems are often largely reduced to a count of species richness. Ideally this would consist of a complete inventory of the species occurring in the area under consideration. In practice, this is unrealistic even for small areas, as smaller invertebrates and micro-organisms can rarely be enumerated comprehensively. Species richness measures will therefore in practice be based on samples, especially of macro-organisms. It must, however, be stressed that species richness itself is an inherently flawed measure of biodiversity as all 'species' are not equal either conceptually (see Section 2.1.4) or with respect to the extent of diversity they represent (see Sections 2.3.2.2 and 2.3.2.3) (Harper and Hawksworth 1994). The following discussion has to be seen in this context.

Although simple measures of species richness contain little ecologically important information, in the case of macro-organisms they are in practice the most easily obtainable, and are thus often the only available general index for comparisons of biological diversity. More sophisticated measures of diversity (see Section 2.3.2.1.3) take into account the relative abundance of the species concerned. These tend to assume that an area is more diverse the more equally abundant are the species present, but different models often generate different diversity measures from the same sets of data (Magurran 1988). In addition, weight can also be given to the relative abundance of species in various categories, for example different size classes, different trophic levels, different taxonomic groups, or different growth forms (see Section 2.3.2.3). Thus a hypothetical ecosystem which consisted only of several species of primary producers, such as

photosynthesizing plants, may be considered less diverse than one with the same number of species but which included herbivores and predators. Similarly, an ecosystem with representatives from four different phyla would be phylogenetically more diverse than one with representatives of only two. A number of diversity indices have been developed which variously give higher weight to basal or relict groups (Sections 2.1.6 and 2.3.2.2), or to particularly species-rich higher taxa (see review by Faith 1994).

3.1.1.5 Comparisons of different areas

Given a satisfactory measure of diversity, it should theoretically be possible to compare the diversity of different areas. However, such comparisons are not entirely straightforward. Diversity measures for ecological entities such as communities or ecosystems make the assumption that these entities are not site-specific, that is, that they occur in essentially the same form over a wide area or in a number of different places. While this may be essentially true of physical and functional characteristics, species composition and species abundance are very rarely constant either in space or in time; thus the existence of communities or ecosystems definable by species composition is seriously questioned by many ecologists. This undermines the extent to which diversity measures derived from particular sites can be used as a basis for generalization. Nevertheless, these ecological concepts still retain considerable force, even if they cannot be rigorously defined, and much discussion of biological diversity is couched in terms of comparisons between different habitats and ecosystems (see 3.2).

The overall diversity of any given area will be a reflection both of the range of sites or kinds of habitat it includes, and the organismal diversity of these components. The differences between habitats in terms of species composition are referred to as beta (β) diversity, while the diversity within a site or habitat is alpha (α) diversity (see Section 2.3.2.1 for fuller definitions). Thus an area with a wide range of dissimilar habitats will have a high-diversity, even if each of its constituent habitats may have low diversity. An area with relatively low species diversity will make an important contribution to the overall diversity of the larger region it is found in if it contains a significant number of species that do not occur elsewhere (endemics). Mountain ranges and oceanic islands are familiar examples of areas that often have comparatively low species diversity but high rates of endemism.

3.1.2 Organism inventory

3.1.2.1 Inventorying life: the pivotal role of species

With few exceptions, inventories of the living world involve named taxa, from the level of Domain or Kingdom down to the various infraspecific (below species level)

categories. For any comprehensive assessment of the richness of life on Earth, diversity at higher classification levels (see Section 2.3.2.2) and of infraspecific entities (see 3.1.3) form essential parts of the picture, but the traditional focus of local, regional and global inventory efforts for most groups of organisms has been at the level of species. Lists of species (see Section 8.4.4, Box 8.1-1) are the common threads that link formal catalogues of life's diversity to all studies of natural assemblages. Species remain pivotal to the practical task of documenting biological diversity, as exemplified in such recent initiatives as *Systematics Agenda 2000* (1994) with the mission '*to discover, describe and classify the world's species*' (our italics). This pivotal role is occupied for arguably sound theoretical as well as operational reasons (Stanton and Lattin 1989).

The advantages of employing a 'biological' species concept wherever practicable in quantification of biological diversity at the species level have been detailed by Wilson (1992) and further discussed by Hammond (1995), who stressed the feasibility and value of establishing rough equivalence of the units used to quantify diversity in clonal organisms and micro-organisms in general to the biological species recognized in those organisms where interbreeding criteria apply. However, it is increasingly suggested, mostly by microbiologists themselves (e.g. Embley *et al.* 1994; O'Donnell *et al.* 1994), that quite different approaches to the quantification of microbial diversity are needed. None that is compatible with macro-organism approaches has so far been proposed but, given the existing conceptual impasse, a serious search for an alternative basis for measuring diversity is clearly desirable. Whether any alternative, once established, might then properly replace the use of species counts remains an open question. There are, of course, entirely different ways of assessing biological diversity as a whole that do not involve taxonomic hierarchies as such, but span the sweep from intrapopulation genetic diversity to ecosystem diversity (Solbrig 1991; May 1994a). There are also ways involving species that place emphasis on various aspects of diversity, such as the equitability of samples drawn from an assemblage, other than richness *per se*. However this may be, the question of how many kinds of organism there are (in this case 'kinds' being biological species or their rough equivalents) is still the logical focus of any attempt to assess the progress that has been achieved to date in compiling a working inventory of living organisms.

The aim of this subchapter is to assess how accurate a picture of the richness of life on Earth in terms of species is provided by the existing formal but very incomplete inventory. Two separate but often intertwined questions are involved: how good is the existing inventory in its own terms as an avowedly partial account, and how accurate a perception do we have of the size of the remaining

descriptive task? Consideration of the second of these questions is largely deferred to 3.1.1.3, while the first is discussed in 3.1.1.2, with reference to a series of other questions:

- How sound are the taxonomic hypotheses, especially those concerning species limits, on which the existing partial inventory is based?
- How well organized into catalogues and monographs are the results of the descriptive effort to date and how accessible are they?
- Which parts of the formal record are relatively complete? In what manner and at what rate is the record improving?

3.1.2.2 *The record to date: described species*

The existing species record is deficient in several respects (Hammond 1992): it is partial (many species have not been described), inaccurate (it contains errors of taxonomic judgement and of many other kinds), and biased (it is clearly more complete and more accurate for some groups of organisms and for some biomes, for example, than for others). It is therefore prone to mislead, not least when used directly or indirectly as a basis for any estimate of overall species richness, including species that are as yet undiscovered and/or undescribed (see 3.1.2.3).

In addition to being incomplete and in parts unsound, the record to date is deficient in its own terms. For many groups, data on described species are so poorly organized that the number of currently recognized species is often only very approximately known. Not surprisingly the figures for described species given, even in high profile reports and ostensibly authoritative works, vary considerably (for examples see Hammond 1992, 1995; Gaston 1991a, b), and are almost always, and notably with respect to some of the larger invertebrate animal groups, out-of-date, due to delays in cataloguing. However, even where reasonably reliable figures are available, channels for communicating these data function poorly. Furthermore, the common use of figures seemingly plucked from the air, including sometimes even figures from the same work (e.g. Brusca and Brusca 1990) that are mutually contradictory, fosters the impression that the accuracy of described species totals is not generally a matter of great concern to many who make use of them. In most recent instances the figures provided for the overall number of species currently recognized as valid tend to be put at around the 1.4 million mark (e.g. Arroyo *et al.* 1992; Wilson 1992). On investigation, however, this number is seen to be based on catalogues and estimates that are in many cases well out of date. Using the most up-to-date catalogues available and other literature sources to make

fresh individual counts or estimates of all major groups, and benefiting from advice from a range of relevant specialists, Hammond (1992) settled on a figure of approximately 1.7 million currently recognized species. With piecemeal revision of the figures for some of the larger but poorly catalogued groups, and with allowance for growth in the interim, the total arrived at and used here is approximately 1.75 million (see Table 3.1-1). This, however, remains conservative, as several of the tallies used for individual groups, including the already large one of 400 000 species for the Coleoptera (beetles), may well be underestimates (Hammond 1992).

The precision of species counts for the larger groups of organisms remains extremely variable (Hammond 1995, and see Table 3.1-2), with those for chordates, bacteria (Dworkin 1992; Trüper 1992) and viruses, for example, very high. As a result of recent attention, estimates for fungi (Hawksworth 1991a, b), although still bedevilled by imprecision due to the separate naming of the asexual stages, and those for land plants, are now both much improved. Precise counts are not available for the Protoctista, but the approximate number of recognized species is tabulated for each of the major groups of eukaryotic algae by Andersen (1992) and for major 'protozoan' groups by Vickerman (1992). Figures that may be moderately reliable for many of the marine or largely marine 'invertebrate' animal groups may be arrived at by using standard sources (e.g. Barnes and Hughes 1982; Barnes 1989) and recent reviews (Minelli 1993; Winston 1992) as a starting point, up-dating and revising the figures provided as appropriate and where feasible. However, some of the most striking remaining uncertainties involve the largest groups of invertebrates.

For the Mollusca, for example, the number of described species currently accepted is particularly problematic, with quoted figures ranging from some 45 000 to 150 000 (Minelli 1993). Winston (1992) gives 75 000 as the figure for the marine species of Mollusca alone. The problems in assessing whether the true figure lies even within the wide range of these estimates stem from the large number of mollusc names that are synonyms or refer to categories below the species level, a paucity of modern catalogues or monographs, and the lack of systematic reporting of newly established synonymy in the *Zoological Record* or elsewhere. The relatively large number of recent fossil taxa of molluscs complicates the issue further.

For nematodes also, in the absence of complete catalogues, the number of described species currently regarded as valid cannot be determined at all reliably. However, based on the figures provided by Gerlach (1980) and Poinar (1975, 1983) with the addition of subsequently described species (see *Zoological Record*) a figure of around 25 000 is reached. As with the Mollusca, new synonymies are not systematically recorded for Nematoda by the *Zoological Record* but these are assumed to be relatively few.

Table 3.1-1: Partial classification of living organisms, largely following a recent version of Whittaker’s five kingdom system (Margulis & Schwarz, 1988), except that the prokaryotes are divided into two domains of equal rank – the Archaea (Archaeobacteria) and Eubacteria or ‘true’ bacteria. To this classification are added the viruses: minute and generally parasitic sub-organisms apparently derived from the nuclear materials of other life forms. The Margulis and Schwarz system is only partially phylogenetic: the Protoctista, for example, comprises all those eukaryotes that are not plants, fungi or animals, and the group is clearly not monophyletic. All groups equivalent to Phylum level or above with more than 5000 described species are included in the list and are marked with an asterisk (*). The approximate number of currently accepted described species is indicated for each of these groups. † Total includes Archaea.

EUBACTERIA	[c. 4 000]†	ANIMALIA*	1 320 000
(bacteria, cyanobacteria ‘blue-green algae’, etc.)		MESOZOA	
ARCHAEA		METAZOA* 1 320 000	
(halobacterians, methanogens, eocytes, etc.)		Porifera* (sponges)	10 000

PROTOCTISTA*	80 000	(hydras, jellyfish, corals, etc.)	
(‘protozoa’, ‘algae’, etc.)		Platyhelminthes*	20 000
Actinopoda*	6 000	(flatworms)	
Foraminifera*	10 000	Nematoda* (roundworms)	25 000
Ciliophora*	8 000	Echinodermata*	6 000
Sporozoa*	5 000	(sea urchins etc.)	
Rhodophyta* (red algae)	5 000	Chordata*	45 000
Gamophyta* (green algae)	10 000	(fish, birds, mammals, etc.)	
Bacillariophyta* (diatoms)	12 000	Arthropoda*	1 085 000
PLANTAE*	270 000	(crabs, spiders, insects, etc.)	
(land plants)		Mollusca*	70 000
Mosses and liverworts*	16 000	(snails, squids, etc.)	
Pteridophytes* (ferns)	10 000	Annelida*	12 000
Spermatophyta* (seed plants)	240 000	(segmented worms)	
FUNGI*	72 000	VIRUSES	[c. 4 000]
(moulds, lichen-forming, yeasts, mushrooms, etc.)			

With few totals for major groups (see Hammond 1992) likely to be astray by more than about 20%, the degree of uncertainty with respect to the number of currently recognized species of arthropods is substantially lower than for some other invertebrate groups. Nevertheless, with more than one million described species currently recognized, inaccuracies in tallies for major arthropod groups may have a profound effect on the total arrived at for the biota as a whole. Unfortunately, although the means to perform the task are available (relatively good and numerous catalogues, recording of new synonymy and other changes in the status of names in the *Zoological Record*, and a formidable body of expert input to call upon), accurate and up-to-date counts for most large arthropod groups are lacking. Of the four largest insect Orders, the figures for Diptera (*c.* 120 000) and Hymenoptera (*c.* 130 000) (see Gaston 1993) provided by

Hammond (1992) are probably more reliably based than those for Lepidoptera (*c.* 150 000) and Coleoptera (*c.* 400 000). Many of the uncertainties with respect to the Lepidoptera stem from the much greater number of available names (including synonyms) than of recognized species, and continuing confusion between totals for the two in some of the largest groups such as the Noctuoidea. Uncertainties as to the true figure for Coleoptera arise because the intimidating yet essentially straightforward task of making new direct counts has been done for only a small number of families, coupled with the finding that there are large discrepancies between ‘accepted’ figures based on catalogues of various dates and those arrived at by making direct counts in the instances where these have been made (see Hammond 1992).

In those groups of organisms where an evidently low priority has been accorded, even by the taxonomists

Table 3.1-2: Approximate numbers of described species (in thousands) currently recognized, and estimates of possible species richness for groups of organisms with more than 20 000 described species and/or estimated to include in excess of 100 000 species. Low and high estimates are given from a variety of sources (see text), along with conservative ‘working figures’, updated from Hammond (1992). Numbers are rounded to the nearest thousand, five thousand, etc. Higher figures than the highest included here have been proposed for some groups (*) by extrapolating from the contents of small samples of soil/mud from deep ocean sediment samples (e.g. Grassle 1991; Grassle and Maciolek 1992), or by extrapolating from certain assumptions that have been made with respect to the specificity and loads of parasites in invertebrate hosts. The somewhat arbitrary working figures for bacteria and fungi are those widely accepted by specialists in these groups. The reliability of all estimates, including the working figures provided here, is likely to vary greatly. Their probable accuracy is indicated in the column to the right of the table. Working figures are categorized as either almost certainly accurate within a factor of 2 (Good), within a factor of 5 (Moderate), within a factor of 10 (Poor), or not certainly within an order of magnitude (Very poor).

Described species		Number of estimated species		Working figure	Accuracy
		High	Low		
Viruses	4	**1 000	50	400	V. poor
Bacteria	4	**3 000	50	1 000	V. poor
Fungi	72	**2 700	200	1 500	Moderate
‘Protozoa’	40	**200	60	200	V. poor
‘Algae’	40	*1 000	150	400	V. poor
Plants	270	500	300	320	Good
Nematodes	25	**1 000	100	400	Poor
Arthropods					
Crustaceans	40	*200	75	150	Moderate
Arachnids	75	1 000	300	750	Moderate
Insects	950	100 000	2 000	8 000	Moderate
Molluscs	?70	*200	100	200	Moderate
Chordates	45	55	50	50	Good
[others	115	800	200	250	Moderate]
Totals	1 750	111 655	3 635	13 620	V. poor

involved, to keeping track of how many species have been described, the reasons are generally clear (Hammond 1995). Foremost among these is that already described species represent an uncertain but generally relatively insignificant portion of the total that actually exist. In many instances also, described species have little more than a notional presence in the accumulating catalogue of life. Their names may appear in catalogues or lists but they are not immediately recognizable entities even to taxonomists (LaSalle and Gauld 1992). Leaving to one side the best-known groups such as vertebrates and plants, it is reasonable to estimate that perhaps 90% of described species have never been included in a regional fauna or flora, an identification manual or a thoroughgoing modern monograph of a well-defined taxonomic group. Not surprisingly, the existing inventory of described species

contains relatively large amounts of ‘hidden synonymy’ (Hammond 1992; Gaston and Mound 1993).
The absolute rate at which the existing species inventory is growing may be assessed very roughly by considering the rate at which new species are being described, currently in the region of 13 000 or so per annum. The most striking feature of the description rate, even for individual groups (see Figure 3.1-1) is its constancy over time-scales of one or two decades. For example, the mean figure for newly described animal species (including ‘Protozoa’) for the years 1979–1988 (data from the *Zoological Record*) is 11 599, with the highest figure for any of those years 12 365 and the lowest 10 912. Crude ‘growth’ rates (the number of new species described in relation to the number already described) also vary relatively little from group to group, but provide some measure of how existing inventories are

Figure 3.1-1: Description rates over a ten-year period 1979–88 for the groups of organisms with the highest rates, illustrating how invariant these are. The differently shaded areas represent (from top to bottom): Coleoptera (beetles), Arachnida (spiders, mites, etc.), Hymenoptera (wasps, ants, etc.), Diptera (two-winged flies) and Hemiptera (bugs). (Based on data in the *Zoological Record*.)

improving. Hammond (1992, 1995) provides further discussion of these rates and their possible significance for the remaining descriptive task, while more detailed analyses of past and present patterns of description have been made for several individual taxonomic groups (e.g. Gaston 1991b, 1993).

However, despite the high rates of description, increments in the numbers of species recognized as valid, especially in some of the more poorly known groups, may be much lower. This is largely due to the recognition, on critical study, that some previously described species are in fact the same as other described species, and their subsequent relegation to synonymy (Gaston and Mound 1993). For the insects the *Zoological Record* routinely lists newly established synonymies and other changes in the status of names so that, with some effort, the actual increment in species recognized per annum may be ascertained. Synonymy rates may be quite high. For example, in 1979, 2116 beetle species were newly described, but in the same year some 426 beetle species were referred to synonymy. Taking into account also additional small numbers of species resurrected from synonymy, subspecies raised to specific rank and species downgraded to subspecies, the net gain of Coleoptera species for the year was 1689, i.e. some 80% of the new species total. Gaston (1991a) quotes synonymy rates for the four major insect Orders for the years 1986–87 and 1988–89 which are variable but on average around one-third of the number newly described in those years. The relationship between numbers of species newly described and the number synonymized clearly depends very heavily

on how taxonomic efforts are deployed and, ultimately, on what in publication terms is fashionable.

3.1.2.3 The true richness of life

Detailed discussion of this topic has centred mainly on the world of animals and plants, frequently ignoring micro-organisms or relegating them to footnote status. Although the question of micro-organismal diversity is now emerging from this neglect, very few pertinent data are available on which serious discussion of the topic might be based. In addition, some authorities have questioned the applicability, in this context, of concepts such as the biological species, which are well suited to assessing the diversity of animals, plants, but rather less so to many fungi and microorganisms (see 3.1.2.1).

Given the uncertainties that persist with respect to bacteria and other clonal microorganisms in particular, but also other groups such as nematodes and mites, and whole biomes such as the deep ocean benthos (see below), current understanding of the overall dimensions of global species richness is understandably imprecise. Nevertheless, the question has been reviewed extensively and critically examined at some length (Hammond 1992, 1995).

Working figures for the number of existing species in the groups likely to make the greatest contribution to the total are illustrated in Figure 3.1-2 (after Hammond 1992, with some small revisions), and some idea of the range of existing opinion on the number of existing species in the more significant groups is provided in Table 3.1-2. To evaluate the contrasting estimates and views on the topic it

Figure 3.1-2: Numbers of described species and conservatively estimated existing species for major groups of organisms expected to contain in excess of 100 000 species (see Table 3.1.2-2 and Hammond 1992). Vertebrates are included for comparison. Note that the white portion of the bar for insects is truncated so as not to unbalance the diagram, and the length of the undescribed species portion is particularly speculative for the various groups of microorganisms.

is necessary to examine the types of evidence that have been used or might be used in arriving at them.

First, the question of the number of existing species may be approached by examining the record to date. Unfortunately, the biases in this record mean that the pattern of description is likely to be uninformative. Trend lines with respect to the rate of accumulation of new species are misleading at best (Frank and Curtis 1979; Simon 1992; Hammond 1992). The important data are those for the most species-rich groups, although species richness patterns in some of the less rich groups are of interest in themselves where these groups are of significance for conservation. It is unreasonable, however, to expect these latter data (on groups such as mammals and plants) to fulfil an 'indicator' role for species richness patterns in general.

Secondly, hints and indications (not reliable estimates) may be derived by extrapolation from what we know of body size relationships, biogeography, range sizes, the nature of mutualisms and other obligatory associations between species, latitudinal and other gradients, the influence of biotic and abiotic variables, community structure, and a range of other factors.

The question of the extent to which the well-established relationship between body size and species richness that

obtains for at least the better-known animal groups (Van Valen 1973; Dial and Marzluff 1988; Marzluff and Dial 1991) may legitimately be extrapolated to the less well known groups which predominate in the smallest size classes, has been posed and discussed particularly by May (1978, 1988, 1994b). While it is clear that for each major group of organisms there is an optimum size range and that within this range more species are generally found at the smaller end, it is also clear that there is a minimum size for each of these groups and for organisms overall (Hammond 1995). It remains questionable whether the very smallest size classes (those characteristic for many micro-organismal groups) include very many species. In part, the answer to this question depends on the kind of 'species' we recognize in such groups, but there are a number of sound biological reasons why the smallest size classes may be expected to contain fewer species than the not quite so small, notably the probably large average geographical ranges of very small organisms (supported by numerous observations) (Fenchel 1993).

Thirdly, data with respect to samples taken from appropriate natural assemblages have been employed in a variety of ways to estimate the species richness of various groups by extrapolation. For example, attempts have been made to use ratios of described to undescribed species in large

Box 3.1-1: Using simple ratios as a basis for extrapolating species richness in poorly-known but species-rich groups (data abridged from Hammond 1994).

The use of ratios involves the assumption that what holds in one instance also holds in another. It cannot be taken for granted, when dealing with species-richness ratios, that this assumption is always well grounded. It follows that essential features of this approach are the calibration of ratios, ensuring that like is compared with like, and the fullest use of ‘hands on’ knowledge of the groups in question and the settings in which they are found. Appropriate selection and use of focal groups for extrapolation to larger groups, the choice and use of sampling methods to obtain reliable sample data from which to extrapolate, and rigour in assembling the species data sets that form the basis of estimates, are also vital.

Species-richness ratios involve groups and contexts or settings in various ways. The ratios of greatest utility fall into six general categories:

- | | |
|---|---|
| • Group A to group B (e.g. butterflies to beetles). | • Area A to area B (e.g. site A to site B). |
| • Subgroup to group (e.g. butterflies to insects). | • Smaller scale to larger scale (e.g. site to country). |
| • Sample to inventory (e.g. of a site). | • Habitat/stratum to inventory (e.g. of a site). |

samples from a defined area (Hodkinson and Casson 1991; Hodkinson 1992; Hodkinson and Hodkinson 1993). Ratios of the species richness known to obtain at different spatial scales in ‘well-known’ groups, especially birds, mammals, land plants or butterflies, have also been used as a basis for extrapolation to less well-known but species-rich groups, for which at least one or more data points are available (Hawksworth 1991a; Gaston 1992; Hammond 1992). In some instances, sample data for poorly-known groups have been used on their own to extrapolate across spatial scales (e.g. Grassle and Maciolek 1992). The value of these and other methods of estimating species richness of poorly explored but diverse groups of organisms has been reviewed critically by Hammond (1994, 1995), who concluded that the use of appropriate samples calibrated against inventories, and simple ratios of species richness between the group under investigation and a carefully selected, and generally less inclusive, ‘reference’ taxon or group provided the most practical and reliable approach (see Box 3.1-1).

How useful in making species richness estimates are the new sample data that have been pressed into service? Some are clearly more valuable than others, with the value depending very much on how they are gathered as well as on how they are then used. Interpreting the possible significance of some is not easy (e.g. data on parasite or parasitoid loads or specificities, on food-web structure, or uncalibrated data from canopy insect samples). Unfortunately, very often the patterns revealed appear to say more about how the data are gathered than they do about general patterns in nature.

3.1.2.4 Sources of undisclosed species richness

Despite widely differing views on the scale of overall global species richness, there is probably general

agreement as to the taxonomic groups and biomes that might contribute very extensively to the global species total. It is the relative contributions of these ‘uncharted realms’ that are in contention.

3.1.2.4.1 Benthic species richness. Suggestions that the marine benthos harbours vast numbers of undescribed species have emerged from relatively recent findings that high local species richness is characteristic of the macrofauna from deep ocean sediments (Grassle and Maciolek 1992), as well as from the indications of possible great species richness of microorganisms revealed by recent studies of little or previously unknown groups (Giovannoni *et al.* 1990, Fuhrman *et al.* 1992). On the basis of extrapolations made from sample data from such sediments, it has been argued that the marine macrofauna might number 10 million or more species, but there have been a number of critical responses to these suggestions (e.g. May 1992). The accumulation of species with increased sampling effort observed by Grassle and Maciolek (1992), although involving a geographical transect, has a very uncertain relationship to area (Hammond 1994). Rex *et al.* (1993) conclude simply that the sample data available are inadequate for any estimate of benthic species richness at larger spatial scales.

If the extrapolations made by Grassle and Maciolek (1992) with respect to the benthic macrofauna are indeed reasonable, the species richness of certain benthic meiofaunal groups and microorganisms might reasonably be assumed to be even greater. For example, Lamshead (1993) has noted that samples of macrofauna and meiofauna from marine sediments have similar rarefaction curves, and that nematodes (the major component of the meiofauna) are generally around two orders of magnitude

more abundant in such samples than polychaetes (a major component of the macrofauna). With an increase in abundance of two orders of magnitude representing an increase in diversity of approximately one order of magnitude, it might be expected that the deep ocean benthos contains around one order of magnitude more meiofaunal than macrofaunal species. Lamshead (1993) concludes that extrapolations of the Grassle and Maciolek type point therefore to the existence of around 10 million marine nematode species.

Although patchy distributions at small scales have been well demonstrated for organisms inhabiting deep ocean sediments, typical range sizes for these, as well as for pelagic species, appear to be large, as compared with terrestrial organisms. Extensive geographical ranges are exhibited even by some of the very specialized species associated with the deep hydrothermal vents which are scattered in occurrence through the oceans. If many marine species, especially those of the deep ocean benthos, are indeed broadly distributed, high species richness at small and very small scales is not to be expected to translate to exceptionally high regional or global marine diversity.

3.1.2.4.2 Terrestrial arthropods. With well over one million species already recognized (Table 3.1-1, Figure 3.1-2), the firmest evidence for great richness of existing species is provided by the terrestrial arthropods. Conjectures as to the number of terrestrial arthropod species remaining to be described range from around one million to more than 100 million, but the more securely based of these point to a narrower range of between 2–3 and 20 million. The main focus of the more serious studies has been the insects and in particular the large orders of endopterygotes. As in other areas, several sources and types of evidence have been adduced to provide varying estimates and these have formed the basis for a lively if relatively low-profile debate. The approach adopted by Gaston (1991a), of simply consulting a range of specialist opinion, although branded as unscientific by Erwin (1991) (see Gaston 1992 for a reply), has the merit of avoiding reliance on a single set of sample data (e.g. Erwin and Scott 1980; Erwin 1982; Hodkinson and Casson 1991) of questionable utility for any attempt to directly assay the scale of global insect species richness (Hammond 1992, 1995). Arguing from additional evidence as well as a selection of specialist opinion, Gaston (1991a) presents a convincing case that evidence for the existence of ‘several tens of millions’ of insect species is lacking. While wisely refraining from any precise suggestion, he concludes that a figure of less than 10 million for global insect species richness ‘seems more tenable, and one of around five million feasible’. Note, however, that this conclusion is based on underestimates, some by as much as a third, for the numbers of species already described in many of the more significant insect groups (Hammond 1992, 1995). Gaston himself (1991a) notes that minimum estimates are more

readily constructed than are upper limits to species numbers and accepts as plausible that figures proposed by specialists for some groups are indeed conservative. This argument is more vigorously pursued by Hammond (1992, 1995) in discussing the track record of ‘taxonomists’s opinions’ in assessing the true richness of as yet poorly-known groups with which they work. The record is clearly one of over-cautiousness.

Overall, in contrast to the situation with micro-organisms, fungi and deep ocean nematodes, the more acceptable of recent estimates of the number of existing terrestrial arthropod species are, in fact, remarkably precise. Although a value judgement that has not been fully or coherently justified in print, a figure of around 10 million existing terrestrial arthropod species appears likely to be correct, not only within an order of magnitude but within a factor of two or three. In addition, the agenda for further improving our understanding of the richness of very species-rich groups that has now been clearly articulated (Hammond 1994; Colwell and Coddington 1994) is most immediately applicable to terrestrial arthropods (Hammond 1990; Hammond and Owen 1995; Longino 1994).

The question of just how terrestrial arthropods contribute to the planet’s overall species richness remains, of course, a separate issue, and one that is more dependent on improvements in the understanding of other groups, especially microorganisms, than on better documentation of the richness of the arthropods themselves.

3.1.2.4.3 Tropical tree crowns. Despite much hyperbole, clear evidence is lacking that the contribution of the undoubtedly rich assemblages found in tree crowns is critical to estimates of overall richness of insects or other hyper-diverse terrestrial groups.

3.1.2.4.4 Fungi and other microorganisms. Despite considerable recent discussion, there are still very few hard data to go on for most groups. For fungi the topic has been widely explored by Hawksworth (1991a), who tentatively suggested a conservative figure of 1.5 million for this group. Higher figures have been suggested, as discussed in Hawksworth (1993), but doubts concerning the way in which fungal species richness scales up have led some non-mycologists to suggest that the undoubtedly high local species richness of fungi may not translate to such a high overall figure (May 1994b). However, figures of this order are now generally accepted by mycologists (e.g. Rossman 1995), and no allowance was made in Hawksworth’s calculations for fungi associated with estimated undescribed insect numbers, nor for the increasing realization that fungal morphospecies not uncommonly include more than one biological species (e.g. Brasier 1986).

In the case of bacteria, the perception of how many species might exist has been changed dramatically between 1991 and 1995 as a result of the increased use of molecular technologies on environmental samples. While there may

be only up to 30 000 culturable bacteria, studies on sediments in Norway, especially those by Torsvik *et al.* (1990a, b) have been taken to indicate that unculturable bacteria may be two orders of magnitude higher (Trüper 1992).

Some of the problems and needs for the future exploration of microbial diversity are discussed below. Empirical relationships between size and species richness, which are of particular relevance to microorganisms, are discussed above.

3.1.2.4.5 Other groups. The nematodes, especially those in marine sediments (see 3.1.2.4.1) and soils, are clearly grossly under-recorded, and in addition the extent of specificity in the estimated myriads of undescribed insects is obscure. The estimates that numbers may exceed 400 000 are, however, speculative rather than based on calculations using stated assumptions.

3.1.2.4.6 Mutualists and parasites. Whereas evidence is lacking that free-living freshwater and terrestrial microorganisms (see 3.1.2.4.4) and nematodes (3.1.2.4.5), as well as their marine counterparts (3.1.2.4.1) are as species-rich as terrestrial arthropods (3.1.2.4.2), those that are symbionts or parasites of these same arthropods and other relatively large groups such as the plants could outnumber their hosts in terms of species richness. Views similar to those of Fenchel (1993) that 'symbionts and parasites probably represent the largest pool of undescribed species' are common. Indeed, if, as suggested by May (1994b), it may reasonably be argued that there is at least one specialized species of parasitic nematode, protozoan, bacterium or virus for each metazoan or vascular plant, the numbers of undescribed mutualists and parasites are likely to outnumber greatly undescribed metazoans. This is implicit in contentions such as those of Trüper (1992) that 'we can be sure that the intestinal microbial floras ... contain at least one new species of bacteria in every species of insect' or Embley *et al.* (1994) that 'all arthropods harbour microorganisms and experience suggests that in each case at least some of these will be unrecorded'. However, like other broad generalizations, the existence of a truly vast number of undescribed endosymbionts of the most species-rich free-living metazoan groups, notably the arthropods, remains very uncertain (Brooks and McLennan 1993) and for at least some other parasite groups very doubtful (Hammond 1995).

3.1.2.5 Problems and prospects

Explanations for observed patterns (see Sections 3.2 and 4) should go hand in hand with documentation and test (reciprocal illumination), but there is a tendency for the grand explanation to leap too far ahead of gathering appropriate and pertinent data. Most of the available data with respect to species-richness patterns (see Section 2.3) concern taxonomic groups, habitats and parts of the world

that are likely to be unrepresentative. The problems and prospects for more reliable estimates therefore merit review.

3.1.2.5.1 Well-known groups are poor reference points. There is a general lack of concordance between patterns for the well-known (and species-poor) groups and the hyper-diverse groups. This is true in terms of where peak richnesses occur, and also in terms of the nature – and more importantly the slope – of gradients. In view of the many differences between well- and poorly-known groups, especially the smaller average body size and greater general reliance on water among terrestrial species of the latter, these differences in species-richness patterns are not surprising. Differences in patterns of complementarity, and consequently how species richness scales as the area considered is increased are also likely between well-known and many poorly-known groups. In sum, any concordance in species-richness patterns between groups of very different biologies cannot safely be assumed, especially when these patterns extend across spatial scales.

3.1.2.5.2 Undisclosed sources of species richness. Few newly revealed sources of previously unknown organisms are especially rich in species. However, there is a tendency for any new situation that is found to harbour at least a modest number of species to be seen as a potential source of great richness. Data with respect to poorly-known groups or habitats almost always derive from a limited number of samples, often from only one or a few sites and it is important to recognize that these can provide no more than what Hammond (1995) referred to as 'indications of possible species richness'. Beyond this, their significance is difficult to gauge. Because they generally furnish no basis for assessing how the richness observed at some small scale translates to larger spatial scales, such data rarely enable even minimum species richness that might occur regionally or globally to be predicted with confidence.

3.1.2.5.3 The scale of uncertainty. The scale of uncertainty is a particular problem with microorganisms (see 3.1.2.4.4), clonal organisms in general, mutualists (3.1.2.4.6), and the deep-sea benthos (3.1.2.4.1). Assemblages of microorganisms and some other small organisms such as nematodes remain essentially remote from those who study them, as these organisms tend to demand special techniques for their extraction from their environments and often also to make them recognizable or available for convenient study. Unfortunately but understandably this means that microbiologists not only still face the difficult task of developing appropriate methods and protocols for sampling the organisms they study in a manner that will shed direct light on their local species richness, and that at successively larger scales, but also inevitably lack the day-to-day familiarity with natural assemblages of these organisms which, for example, may be obtained by those who have this familiarity through

direct observation in the field and/or through frequent handling of quantitative samples from these same settings, be it with lichenized fungi, insects, flowering plants, molluscs or filamentous algae. It is to be expected that this remoteness from the organisms they study and the minute landscapes that these organisms occupy will provide little in the way of guidance to most microbiologists in interpreting the significance of any sample data that are available. Lacking any substantial points of reference (e.g. complete site lists) and untrammelled by direct experience of natural assemblages that might act as a check and guide, the interpretation of fragmentary sample data will be subject to preconception (e.g. all metazoans contain species-specific microorganismal mutualists) and whim (e.g. the assumption that species-richness relationships across spatial scales are similar to those found in better-known groups). To a varying degree, the same difficulties obtain with respect to relatively inaccessible but rich natural assemblages, such as those found in deep ocean sediments and in the crowns of high tropical forest trees, although for both of these, especially the first, the problem is substantially one of cost and, with respect to the second, as pertinent data are steadily being obtained, interpretation of their significance is becoming less equivocal.

3.1.2.5.4 Conceptual and operational issues. Many of the conceptual issues germane to assessments of the magnitude of biodiversity have been raised by Harper and Hawksworth (1994) and are considered elsewhere in this volume. One problem unlikely to be entirely overcome is the lack of uniformity in just what is meant by a 'species'. In addition to difficulties with respect to this basic unit of measurement, there are also a number of confusions that tend to arise from the different aims of various types of research in the biodiversity arena. 'Assessments' and 'appraisals' of various types usually have objectives that make them unsuitable sources of data appropriate for use as building blocks with respect to broad-scale species-richness patterns.

3.1.2.6 The tools for the job

The tools required to inventory the Earth's biota are currently grossly inadequate. This issue has been addressed by many authors (e.g. May 1994b; Gaston and May 1992; Hawksworth and Ritchie 1993) and is discussed in the GBA in Sections 7.4 and 8.10. The inadequacy of the taxonomic resource base currently devoted to discovering, describing and understanding the species of organisms found on Earth, is especially noteworthy (*Systematics Agenda 2000* 1994). Removing this 'taxonomic impediment' is a clear imperative.

We are on the brink of substantially increasing our real understanding of the globe's major species-richness patterns but the overall scale of global species richness and how this richness is broadly distributed, taxonomically and geographically, continue to be regarded as questions of

minor significance by some. And yet, a sound appreciation of these patterns is essential if ideas about the way in which they originated and are maintained (see Section 4) are to be put to any serious test. Nevertheless, even now the number of species of organisms inhabiting the Earth can probably be estimated with some confidence to within about an order of magnitude, the principal centres of richness and endemism (see 3.2 and 3.3) are probably already known, and there are good prospects of this position rapidly improving. As well as obtaining the resources needed to expedite this task, the scientific community now needs to focus on distinguishing the irrelevant and the unsubstantiated from the pertinent and the sound with respect to opinion and data on patterns of biological diversity. Their organizational abilities too need to be directed to communicating the results of good science in this area as promptly and widely as possible.

3.1.3 Genetic diversity

In its broadest sense, genetic diversity embraces the diversity found at all levels of the taxonomic or ecological hierarchies. Species diversity, for example, may be assessed with greater resolution in genetic terms. In practice, however, in the absence of detailed information on the genetic make-up of most species and populations, there is unlikely to be any useful way of quantifying or summing the genetic diversity of large units such as, for example, ecosystems. The main focus of attempts to quantify genetic diversity is thus at the levels of species, populations and individuals. The various ways in which genetic diversity can be characterized or quantified, and the techniques for doing so, are described in Section 2.2, while the role of genetic variability in generating and maintaining the diversity of life is the subject of Section 4.2.

Each species contains an enormous quantity of genetic information. The number of genes ranges from around 1000 in bacteria and 10 000 in some fungi to 400 000 or more in many flowering plants and some animals. The full information contained in the genes of a typical mammal, if translated into ordinary sized letters of printed text, would just about fill all 15 editions of the *Encyclopaedia Britannica* published since 1768 (Wilson 1988).

Genetic diversity can be viewed and compared at three levels:

1. genetic variability between individuals within populations,
2. genetic variability among populations within species, and
3. diversity among species.

The relative proportions of the diversity that are contained at these three levels depend on the evolutionary

Table 3.1-3: Average total expected heterozygosity (H) and the portion of the total heterozygosity due to differences among populations (G_{ST}) in major taxonomic groups (after Ward *et al.* 1992).

	$H^1 \pm SE$	No. of species	$G_{ST}^2 \pm SE$	No. of species
Vertebrates				
Mammals	0.067 ± 0.005	172	0.242 ± 0.030	57
Birds	0.068 ± 0.005	80	0.076 ± 0.020	16
Reptiles	0.078 ± 0.007	85	0.258 ± 0.050	22
Amphibians	0.109 ± 0.006	116	0.315 ± 0.040	33
Fishes	0.051 ± 0.003	195	0.135 ± 0.021	79
Invertebrates				
Insects	0.137 ± 0.004	170	0.097 ± 0.015	46
Crustaceans	0.052 ± 0.005	80	0.169 ± 0.061	19
Molluscs	0.145 ± 0.010	105	0.263 ± 0.036	44

1. Total expected heterozygosity calculated from alleles pooled over samples within species.
2. Proportion of the total expected heterozygosity due to allele-frequency differences among populations.

rates of the proteins or DNA used to measure the variability, on the breeding system, and on the degree of connectivity between populations. The relative proportions of variation between and within populations hold important implications for conservation programmes, as discussed in Section 13. Molecular studies show that most species harbour a wealth of genetic variability (see Section 2.2.0) that may be assessed at the level of individual genetic loci or the genome as a whole (see Section 4.2.2).

3.1.3.1 Animal genetic diversity

For allozyme data, the average expected heterozygosity (H , the proportion of loci that carry two different alleles) in invertebrate species ($= 0.122 \pm 0.004$) is greater than in vertebrates (0.071 ± 0.002 , Table 3.1-3). The chief reason is that more complex organisms tend to have more subdivided populations than less complex ones, and larger populations harbour more genetic variability than small populations at drift-mutation equilibrium. Generally, mammals, birds and reptiles have similar overall levels of genetic variability, whereas amphibians have higher levels and fishes lower levels (Ward *et al.* 1992). Within each group, however, levels of genetic diversity vary considerably because different life-history patterns produce

Table 3.1-4: Allozyme variability in plant groups with various life history attributes (from Brown and Schoen 1992; Hamrick and Godt 1990).

Life history category	No. of species	H_T	H_S	$G_{ST} (F_{ST})$
Mating system (pollination)				
Selfing	78	0.12	0.07	0.51
Mixed				
Animal	60	0.12	0.09	0.22
Wind	9	0.19	0.20	0.10
Outcrossing				
Animal	124	0.17	0.12	0.20
Wind	102	0.16	0.15	0.10
Geographic range				
Endemic	52	0.10	0.06	0.25
Narrow	82	0.14	0.11	0.24
Regional	180	0.15	0.12	0.22
Widespread	85	0.20	0.16	0.21

different amounts of gene flow and different population sizes. Total heterozygosity in a species comprises two components: genetic variability among individuals within populations and variability among populations. A commonly used measure of among-population variability is F_{ST} (or G_{ST}), the proportion of the total expected heterozygosity due to allele-frequency differences between populations (see Section 4.2.2). The mean value of F_{ST} is largest for some molluscs, amphibians, reptiles and mammals; that is, populations of most species in these groups show considerable amounts of population subdivision. About 25–30% of the total variability in the average species is due to genetic differences among populations. However, values of F_{ST} are highly variable, ranging from 0.0 (no variability among populations) to near 1.0 (fixed allele-frequency differences). Birds and insects, on the other hand, tend to show less variability among populations, presumably because of high levels of gene flow between them (Avisé and Aquadro 1982). On average, only 1–10% of the total variability in a bird or insect species is characteristically due to differences among populations. Thus, an understanding of the geographic distribution of genetic diversity is vital to managers faced with decisions about which subpopulations of a threatened species most warrant protection (Waples 1991). Unfortunately, the required genetic information is often lacking.

3.1.3.2 Plant genetic diversity

A larger number of mating systems produces a richer variety of population genetic structures in plants than in

animal species (Hamrick and Godt 1990). For example, wind-pollinated species have higher levels of heterozygosity ($H_S = 0.15$ to 0.20) within populations, on average, than do animal-pollinated plants ($H_S = 0.09$ to 0.12), and both of these groups have higher levels than self-pollinated plants ($H_S = 0.07$) (Table 3.1-4). Because of restricted gene flow between populations, selfing plants show a greater degree of genetic differences amongst populations ($F_{ST} = 0.51$) than species with mixed breeding systems ($F_{ST} = 0.10$ to 0.22) or outcrossing species ($F_{ST} = 0.10$ to 0.20). The geographic range of a plant species is also an important parameter controlling the amount of genetic diversity within and between populations. Plant species with small geographic ranges harbour less genetic variability within populations on average ($H_S = 0.06$) than those with 'narrow' ($H_S = 0.11$), regional ($H_S = 0.12$) or widespread ($H_S = 0.16$) distributions. The importance of allozyme variability in influencing adaptive traits is largely unknown. Experimental studies suggest that there are larger differences among populations in genes that influence adaptively important traits (Bradshaw 1984).

Cultivated species that have been selected for specific traits often have reduced levels of genetic variability, which can make them vulnerable to diseases and inbreeding depression. For example, resistance to downy mildew (*Sclerospora graminicola*) in pearl millet is absent in most cultivars, but was found in related wild strains in Nigeria, the crop's centre of origin. Similarly, resistance to potato viruses, bacteria, fungi and nematodes has been found in wild species of potatoes (*Solanum*) in the Andes Mountains of South America. Genetic diversity in wild species related to domesticated plants must be maintained so that it can be used to improve the characteristics of domesticated plant species (see 3.1.4.6).

3.1.3.3 Other organisms

The extent of genetic diversity in groups other than certain well-studied plant and animal species cannot be assessed accurately at this time. However, it is clear that the extent of such diversity in the fungi and bacteria particularly is considerable, and that it might even exceed that in macro-organisms. Examples of the genetic variation already documented within single microbial species are *Chlamydomonas reinhardtii* with at least 159 mutant lines, *Neurospora crassa* with over 3000, and over 3500 serological types of *Salmonella* (Board on Agriculture 1994). The extent to which such phenomena are widespread in nature is uncertain, but the variation in secondary metabolites of fungal strains isolated from nature is sufficient to have acted as a spur to the isolation of strains for screening programmes.

3.1.4 Domesticated diversity

Domesticated species represent a small fraction of the Earth's biota, but these relatively few organisms provide

well over 90% of human food supplies, as well as meeting many other human needs (see Sections 2.2 and 8.8). Domestication is the process (see Section 2.2.2 for a fuller discussion) by which plants, animals or microbes selected from the wild, adapt to special habitats, created for them by humans. These organisms, or domesticates, breed in captivity for human profit and under at least a degree of human control (Clutton-Brock 1987; Balain 1991; Hemmer 1990). Since the dawn of agriculture, at least 10 000 years ago, plants have been taken into cultivation by humans, many of them chosen for their cooking qualities, tastes or aromas (food plants). Others have been selected for their healing properties, as ornamentals, or in order to use their fibres or woody parts for a variety of purposes. While the first animal domesticate was the dog, other early animal domesticates were kept in flocks and herds so that they could be used as a source of food. Sheep and goats were probably the first of these, followed by cattle and pigs, and finally the horse (Clutton-Brock 1987). Domesticated microbes (see Section 2.2) include microbial variants or strains used to make antibiotics and vaccines, as well as those traditionally used to make bread, cheese and wine.

3.1.4.1 Sources and centres of domesticated biodiversity

Domesticated biodiversity may be characterized (see Section 2.2.2.1) as the genetic variation existing among the species, breeds, cultivars and individuals of animal, plant and microbial species that have been domesticated, often including their immediate wild relatives. The term may be extended to include ecosystem diversity where this is dominated by domesticates (Hammond in press).

Although the first genetic changes may have occurred by natural selection, leading in animal domesticates, for example, to adaptation to confinement, increase in tameness, and ease of breeding in captivity, domestication has traditionally been accomplished by selective breeding. Continued artificial selection (see Section 2.2.2) has resulted in an enormous number of different animal breeds, each characterized by its unique adaptive traits and useful properties, but without excessive loss of fitness or adaptability (Mace 1990; Balain 1991).

As with animal species, the diversification of crop plants has been dependent upon the existence of genetically different forms on which selection could act, and in addition to the automatic selection pressures, humans have intervened by applying deliberate and intentional processes of selection. In most crop plants, diversity is generated through hybridization and recombination processes between different forms, wild or cultivated. Although in a particular genotype mutations may add to diversity, these are comparatively rare, and in most cases disadvantageous (Bunting 1990). Most fruit and nut trees were brought into domestication by changing the reproductive biology of the plants involved, by

Table 3.1-5: Areas where plants and animals were domesticated. The names in parentheses show that the same species was probably domesticated independently in different areas (from Harlan 1976).

North America	Highland South America	African rice	Goat	Soybean

shifting from sexual reproduction in the wild to vegetative propagation under cultivation. As a rule, cultivated varieties of fruit trees are maintained vegetatively by cuttings, rooting of twigs, suckers, or grafting, and are seldom raised from seed. This is because wild populations and cultivated varieties maintain high levels of heterozygosity, so that seedlings raised from any mother tree segregate widely in numerous traits. Consequently, and in order to prevent genetic segregation, growers have used vegetative propagation to ‘fix’ desired types (Zohary and Hopf 1993).

Recent advances in molecular biology have enhanced the opportunities for genetic modification of organisms, and speeded up the process of production and selection of new varieties, particularly of microorganisms. New technologies allow the directed production of specific genotypes, sometimes producing specific combinations of genes from organisms that cannot otherwise recombine sexually, e.g. recombinant bacteria (Lenski 1993).

Many plant species now important as crops were first domesticated in (a relatively few) parts of the world often

described as 'Vavilov centres' (see Section 2.2.2). These putative centres of origin are often coincident with centres of diversity within crop species. However, it is now recognized that diversity in a field population or in a region does not necessarily prove that the crop was originally domesticated from wild progenitors that occurred nearby (Harris 1990). For example, there are highly diverse populations of *Phaseolus vulgaris* in Malawi, but there is no doubt that the species was domesticated in the Americas (Bunting 1990).

Centres of origin for animal domesticates, many of them the same as for plants, are also now well established (see Table 3.1-5; 3.2.1.4). Recent studies using archaeological, linguistic and molecular evidence have further documented how plants and animals were domesticated, and how agriculture was developed earlier in some regions of the world than in others (Harris and Hillman 1989). The question of the extent to which agriculture evolved in discrete centres or more or less simultaneously over large areas is considered by Harlan (1971, 1976), Zeven and de Wet (1982), Hawkes (1983), and Harris (1990).

3.1.4.2 Domesticated plant diversity

Of the 511 plant families currently recognized (Brummitt 1992), only 173 have domesticated representatives. Of these, the Gramineae has the largest number of domesticated species with 379 (15.2% of all plant domesticates), mostly originating from the Near East or Africa. The family Leguminosae follows with 337 species (13.5%) of varied origin, including the Indochina–Indonesia region, the Mediterranean coast and adjacent regions, and Central America. Rosaceae ranks third with 158 species, mainly from China and Europe–Siberia; and Solanaceae fourth with 115 species (4.6%), mostly from Central America and Bolivia–Peru–Chile. A notable contribution of domesticates has also been made by the Compositae (with 86 species), Cucurbitaceae (53 species), Labiatae (52 species), Rutaceae (44 species), Cruciferae (43 species), Umbelliferae (41 species), Chenopodiaceae (34 species), Zingiberaceae (31 species), and Palmae (30 species). However, many (about 48) plant families include only one domesticated species (for further information see Zeven and de Wet 1982).

Despite this relatively large number of plant domesticates, 90% of national per capita supplies of food plants come from only 103 species (Prescott-Allen and Prescott-Allen 1990). The most significant of these are domesticated Gramineae (cereals), annual grasses cultivated for their grains. These, together with Leguminosae (legumes), have been the principal crops of most civilizations, and represent the main source of calories. Wheat (*Triticum* spp.) and barley (*Hordeum vulgare*) have been the traditional staples of Europe and western Asia, with the first signs of cultivation appearing in the Near East region in the second half of the 10th

millennium BP. Two more early domesticates were rye (*Secale cereale*) and common millet (*Panicum milliaceum*), followed later by oats (*Avena sativa*). Sorghum (*Sorghum bicolor*) was first domesticated in the African savannah belt, and rice (*Oryza sativa*) in South Asia. The earliest archaeological evidence for the cultivation of these plants is not until the 5th–4th millennium BP and 7th millennium BP, respectively (Zohary and Hopf 1993). Potatoes, maize, *Phaseolus* beans and other New World crops were domesticated by about 7000 BP, and probably earlier.

If we look at biodiversity in terms of species numbers, of the estimated total of 320 000 vascular plants (Fig. 3.1-2), about 3000 are regularly exploited for food. Most of these, some 2500, are domesticated, but only 15–20 are the crops of major economic importance (see Table 2.3 in Ford-Lloyd and Jackson 1986). The distribution ranges of these crops extend across continents, oceans and hemispheres, and show the great diversity of habitats to which migrating crops have adapted over the last 10 000 years.

Within individual species, the extent of selection pressure which humans have applied is illustrated well by *Brassica oleracea*, from which at least seven distinct types of vegetable have been produced. Selection for enlarged terminal buds produced the cabbage; for inflorescences, the cauliflower and broccoli; for the stem, narrow stem kale; for stem tubers, kohlrabi; for lateral buds, Brussels sprouts; for the stem and flowers, calabrese; and for the leaves, kale. Of these, kale most closely resembles the wild plant (Harlan 1976; see also box in Heywood and Chant 1982).

Although the majority of domesticated plants are used as sources of food, some were taken into cultivation for their fibres. In the Old World, two species of cotton (*Gossypium arboreum* and *G. herbaceum*) were the most commonly cultivated plants used for weaving cloth, together with hemp (*Cannabis sativa*) (Zohary and Hopf 1993), although flax (*Linum usitatissimum*) was probably the first to be cultivated. Today jute (*Corchorus* spp.) is perhaps the most important textile fibre after cotton and was domesticated relatively recently to replace hemp. In the New World two species in the family Agavaceae (*Furcraea foetida* and *F. macrophylla*), several species of Malvaceae (*Abutilon oxycarpum*, *Wissadula contracta* and *W. periplocifolia*) and up to six different species of cotton (*Gossypium* spp.) are sources of fibre, and are now cultivated for this purpose elsewhere (Zeven and de Wet 1982).

At least 25 000 plant species in all are thought to be used or have been used for medicinal purposes, but only a few of these are grown as crops. Two examples from the Rubiaceae are *Cephaelis ipecacuanha*, used as a source of ipecac or ipecacuanha to treat amoebic dysentery, and *Cinchona ledgeriana* – with numerous cultivars – a source of quinine for treating malaria (Akerle *et al.* 1991). Others such as thyme, lavender and sage are cultivated as aromatic plants or for culinary purposes, as are numerous spice plants.

Ornamentals, mostly of wild origin but many extensively bred and modified, are also an important and numerous group. For example *The European Garden Flora* project plans to include about 12 000 species, mainly found in cultivation in botanic gardens and specialists collections in Europe. However, at present no complete global inventory of these species exists (Heywood 1992).

Although conventional agriculture and forestry has traditionally concentrated on major crops, tens of thousands of other plants are known to have edible properties. Most of these and many additional species with other useful properties remain undomesticated. Apart from this reservoir of potential future crops, wild plants retain an exceptional importance for agriculture, as wild genetic resources are the key to future production of existing crops. With the help of genetic manipulation and similar new technologies, many crop plants are able to acquire genes from wild species, and develop resistance to pests and diseases (de Groot 1992). Scoones *et al.* (1992) and Wickens *et al.* (1989) cover much of the literature relating to the role of wild foods in agricultural systems, and other under-exploited species respectively and a series of volumes on promising plant species of the Andean sub-region is being published (Correa and Bernal 1990).

3.1.4.3 Domesticated animal diversity

Of the 50 000 vertebrate species, some 30–40 species of mammals and birds comprise a core group of animal domesticates. In addition to dogs and cats, four of the domesticates used as food are found almost everywhere humans have set foot, except for the Antarctic. They are cattle (*Bos indicus* and *B. taurus*), sheep (*Ovis aries*), pigs (*Sus domesticus*) and chickens (*Gallus domesticus*). The global populations of the three dominant mammals are exceptionally large: cattle 1300 million; sheep 1200 million; pigs 850 million. These numbers are exceeded only by chickens, of which there are more than 10 billion world-wide. These wide distributions and vast numbers indicate the unique contribution of these four species to the quality of life in almost all human cultures. Two of the dominant species, one larger (cattle) and one smaller (sheep) are ruminants, whereas pigs and chickens have simple digestive tracts. Two other numerically important ruminants are the domestic buffalo (*Bos bubalus* with its two subspecies, riverine and swamp), and the goat (*Capra hircus*), both of which are also very important in their more specialized locations. Most of the other species in the group of 30–40 are found only in restricted locations. They include species such as the Arabian camel (*Camelus dromedarius*), bactrian camel (*Camelus bactrianus*), Andean camelid species (*Llama* and *Vicuna* spp.), reindeer (*Rangifer tarandus*), yak (*Peophagus grunniens*), mithun (*Bos/Bibos frontalis*) and Bali cattle (*Bos javanicus*) and, of course, a number of bird species. Even with the inclusion

of the species regarded as ‘exploited captives’ rather than true domesticates (Clutton-Brock 1987) such as the Asian elephant, small mammals reared for their fur or kept for other purposes (e.g. the ferret and laboratory rats/mice), various pets and cage birds such as canaries, the number of domesticated species of animals is still small when contrasted with the large number of crop plant species.

These facts may suggest at first sight that the biodiversity of livestock and avian species is somewhat limited. However, over thousands of years an enormous number of different breeds have been developed within each of the major livestock species, each characterized by its unique adaptive and productive traits. For example, Loftus and Scherf (1993) list nearly 800 distinct breeds of cattle and more than 800 different breeds of sheep (and the number recognized by Hall and Ruane (1993) is still higher – see Section 2.2.2.1). Many of these breeds are specially adapted to one of the many environments, differing in climate, topography and vegetation, in which humans live. In addition, a large number of breeds are also recognized in dogs, cats and other species not reared for food, such as pigeons.

Today, in the developed world the livestock sector is responsible for over half the economic output of agriculture. Furthermore, domestic animals in advanced societies also contribute to quality clothing, speciality foods, and to recreation and sport. In developing countries, which generally consume less animal produce per capita (though this is increasing rapidly in many advancing societies, for example in Asia), domestic animals still serve billions of people with important benefits in addition to food. The most important of these is undoubtedly draught animal power. Others include wool, leather, tallow, bone and manure for fuel and for increasing the fertility of cropland. Without the biodiversity and adaptive qualities of domestic animals the majority of humankind in the developing world would still be subject to hard physical labour for crop cultivation and for other traction needs. The large domestic ruminant species, of which the cow and the buffalo are the most numerous, demonstrate particularly well the integration of animal biodiversity with human culture. In addition to provision of labour and milk products and meat for the adult population, the cow and buffalo provide some key benefits such as milk for infants and a backup food reserve in times of leanness and poor crop harvests.

3.1.4.4 Domesticated aquatic biodiversity

Aquaculture is another important aspect of domesticated diversity, with nearly 200 species reared in 136 countries. Species included are freshwater, diadromous and marine fish, molluscs, crustaceans, frogs, turtles and aquatic plants. Aquaculture, with particularly significant contributions from China and Japan, yields over 12 million tonnes

Table 3.1-6: Status of crop germplasm collections (Adapted from Lyman 1984 and Plucknett et al. 1987).

Crop	Number of accessions	Number of distinct samples	Number of collections of 200+ accessions	Number of landraces	Coverage (%) ¹ wild species	Proportion of collected types endangered

1. Coverage percentages are estimates derived from scientific consensus. For wild gene pools coverage relates primarily to those species in the primary gene pool, i.e. species that were either progenitors of crops, have coevolved with cultivated species, continuously exchanging genes, or are otherwise closely related.
- n.a. Data not available.
- * Coverage difficult to estimate because many selections are from the wild.

globally per annum (de Groot 1992). However, although some aquatic species have been exploited continuously from early historic times, few of them truly qualify as domesticates.

3.1.4.5 Domesticated microbial and invertebrate diversity
Interest in microbial and invertebrate diversity in recent years, fuelled by the increasing recognition that vast numbers of insects, bacteria and fungi remain unknown (see 3.1.2.4), has focused on the known and potential value of these organisms to humans, particularly as sources of food and drugs. Their role in sustainable agriculture, for example as biological control agents, and in the detoxification of industrial waste, has also been highlighted (Hawksworth 1991a, b; Jones 1993).

To date, only a tiny proportion of the 72 000 or so described species of fungi and an even smaller proportion of the possible one and a half million or so that exist (see Fig. 3.1-2) have been traditionally used by humans. Of these the most important are yeasts, moulds and mushrooms. Mushrooms were regarded as a delicacy by the Greeks and the Romans, and the first detailed records of their cultivation occurred in the beginning of the eighteenth century, when the French scientist Tournefort described a successful method for growing mushrooms in stable manure (Smith 1993). Their exploitation has now spread to most industrialized countries, with a total annual production now in excess of 1.42 million tonnes (Smith 1993). In addition to *Agaricus bisporus* (the white button mushroom), several other species have been commercially exploited, e.g. *Lentinus edodes* and several species of *Pleurotus*, *Volvariella*, *Auricularia*, *Flammulina* and *Tremella*.

Microorganisms are also used in the processing of dairy products, such as cheese, yoghurt and other fermented

milks and butter. Of these, species of the bacterial genera *Lactobacillus*, *Lactococcus*, *Leuconostoc* and *Streptococcus* are most important, together with yeasts such as *Kluyveromyces marxianus* and *Candida kefir*, and moulds such as *Penicillium camembertii* and *P. roquefortii* (Varnam 1993a).

Other fungal groups are involved in the beneficial fermentation of non-dairy food products. Several zygomycetous species of the genus *Rhizopus* are traditionally used in Indonesia for the fermentation of yellow-seeded soya beans to produce ‘tempe’, which serves as a protein complement to starchy staples. Natural pigments produced by species of the ascomycete genus *Monascus* are also beginning to be widely used as food additives, in place of synthetic compounds (Samson 1993).

Fungi as well as bacteria have been used traditionally in the manufacture of alcoholic beverages, another very highly profitable industry. The most important of these include: *Saccharomyces cerevisiae*, *S. carlsbergensis* and *Schizosaccharomyces pombe*, used in the fermentation of ale-type beer and wine, lager-type beer, and heavy rum respectively; *Aspergillus oryzae* used in the fermentation of sake; and lactic acid bacteria, *Clostridium* spp. and *Enterobacteriaceae* also in the fermentation of beer, wine and rum (Varnam 1993b).

An additional role for microorganisms – in the production of pharmaceuticals – burgeoned following the discovery in the late 1920s of the metabolites produced by the fungus *Penicillium chrysogenum*, and was further encouraged by the discovery in 1949 of cephalosporin produced by another fungus, *Acremonium chrysogenum*. Such metabolites are now known to be produced by about 5000 (c. 7%) of described fungi species, but the search for new drugs and new microbes of use in biotechnology now extends to as yet uncharacterized species. The maintenance

Table 3.1-7: Biodiversity at risk for major food crops (based on Oldfield 1992 with additional data).

Family	Species	Conservation status
GRAMINEAE	<i>Avena sativa</i> (oats)	Unknown
	<i>Hordeum vulgare</i> (barley)	Concern about genetic erosion
	<i>Oryza glaberrima</i>	Many wild relatives lost, especially of <i>O. glaberrima</i>
	<i>O. sativa</i> (rice)	
	<i>Panicum miliaceum</i> (common millet)	Unknown in the wild
	<i>Saccharum officinarum</i> (sugarcane)	Wild relatives lost due to habitat destruction
	<i>Secale cereale</i> (rye)	Unknown
	<i>Sorghum bicolor</i> (sorghum)	Unknown
	<i>Triticum aestivum</i>	Wild relatives restricted to small area
	<i>T. turgidum</i> (wheat)	(need <i>ex situ</i> conservation)
	<i>Zea mays</i> (maize)	Rediscovery of wild relatives; under protection
LEGUMINOSAE	<i>Arachis hypogaea</i> (groundnut)	Unknown; conservation priority
	<i>Cajanus cajan</i> (pigeonpea)	Unknown
	<i>Cicer arietinum</i> (chickpea)	Threatened or rare
	<i>Glycine max</i> (soybean)	Traditional landraces destroyed by modern cultivars; conservation priority
	<i>Lens culinaris</i> (lentil)	Unknown
	<i>Phaseolus vulgaris</i> (haricot bean)	Wild relatives widespread, but some forms need conservation
	<i>Pisum sativum</i> (pea)	Conservation measures limited
	<i>Vicia faba</i> (broad bean)	Unknown
ROSACEAE	<i>Fragaria</i> × <i>ananassa</i> (strawberry)	Unknown
	<i>Malus pumila</i> (apple)	High conservation priority (IPGRI)
	<i>Prunus amygdalus</i> (almond)	Protected
	<i>Prunus armeniaca</i> (apricot)	Protected
	<i>Prunus avium</i> (cherry)	Unknown
	<i>Prunus domestica</i> (plum)	Unknown
	<i>Prunus persica</i> (peach)	Unknown
	<i>Pyrus communis</i> (pear)	Conservation priority (IPGRI)
SOLANACEAE	<i>Capsicum annuum</i> (chili and sweet pepper)	More collection for seed banks needed
	<i>Lycopersicon esculentum</i> (tomato)	Gene pool eroded due to habitat destruction
	<i>Solanum melongena</i> (eggplant)	Unknown
	<i>Solanum tuberosum</i> (potato)	150 wild species; 3000–5000 varieties recognized; conservation priority (CIP)
COMPOSITAE	<i>Carthamus tinctorius</i> (safflowerseed)	The wild relative <i>C. rhiphaeus</i> is rare
	<i>Cynara scolymus</i> (artichoke)	Unknown
	<i>Helianthus annuus</i> (sunflower)	Some preserved; but many still threatened by habitat destruction
	<i>Lactuca sativa</i> (lettuce)	Unknown

CUCURBITACEAE	<i>Cucumis melo</i> (melon/watermelon)	Unknown
	<i>Cucumis sativus</i> (cucumber)	Unknown
	<i>Cucurbita maxima</i> (pumpkin);	Restricted ranges
	<i>C. moschata</i> (squash); <i>C. pepo</i> (gourd)	
LABIATAE	<i>Coleus</i> spp. (Kaffir & Hausa potato)	Unknown
	<i>Ocimum kilimandscharicum</i> (camphor)	Unknown
RUTACEAE	<i>Citrus</i> spp.: <i>C. aurantifolia</i> (lime); <i>C. grandis</i> (pomelo); <i>C. limon</i> (lemon); <i>C. sinensis</i> (orange)	High priority
CRUCIFERAE	<i>Brassica oleracea</i> (cabbage)	Threatened; high priority
	<i>B. napus</i> / <i>B. rapa</i> (rapeseed)	Unknown
	<i>B. juncea</i> (mustardseed)	Large collections available
UMBELLIFERAE	<i>Daucus carota</i> (carrot)	Unknown
CHENOPODIACEAE	<i>Beta vulgaris</i> (sugarbeet)	Threatened
	<i>Spinacea oleracea</i> (spinach)	Unknown
	<i>Chenopodium quinoa</i> (quinoa)	Unknown
ZINGIBERACEAE	<i>Amomum cardamomum</i> (cardamon)	Unknown
	<i>Curcuma heyneana</i> (arrowroot)	Unknown
	<i>Zingiber zerumbet</i> (ginger)	Unknown
PALMAE	<i>Cocos nucifera</i> (coconut)	Genetic erosion in cultivated hybrids
	<i>Phoenix dactylifera</i> (date)	Vulnerable
	<i>Elaeis guineensis</i> (oil palm)	High priority

of microorganismal diversity in the wild (and thereby the array of chemicals they produce) is thus vital for future prospecting (Hawksworth 1991a; Nisbet and Fox 1991).

The part played by microorganisms and invertebrates in sustainable agriculture has also grown in recent years. Some are employed as biological control agents, some as biopesticides, and others for increasing soil fertility (see Hawksworth (1991c) and Jones (1993) for examples). Used for some 50 years as a biopesticide, *Bacillus thuringensis* now accounts for 2.5% of total insecticide production (Dent 1993). However, sales of biological control agents still represent only 1% of the total world market of crop protection products. Enormous scope exists for the development of new beneficial products in this area.

3.1.4.6 Domesticated biodiversity at risk

The diversity of cultivars in many crop plants reached its peak at around the end of the nineteenth century; perhaps somewhat later for some tropical crops. However, this

diversity is now at risk, and the genetic variation (or gene pool) of many crops is eroding. This is due mainly to the development during this century of very uniform cultivars, grown in very uniform environments, created by using the same sophisticated agricultural practices throughout. This would not be much of a problem if the uniformity of crops were not an important factor in the interactions between crops and their pathogens, leading to epidemic outbreaks of disease, and the need for development of new disease-resistant varieties. In the search for new varieties plant breeders are obliged to look outside the narrow gene pool of modern varieties, and rescue forgotten genes from older varieties, or even from wild relatives of the crop. Holden *et al.* (1993) provide various examples of how genetic resources have provided the solution to disease epidemics in major crops such as potato, rice, sweet potato, wheat, maize, sugar beet and rubber.

The total number of cultivated varieties of crops or breeds of livestock is not fully known. Some indication of

Table 3.1-8: World-wide numbers of breeds of the common domestic species of mammals. Figures derived from Loftus and Scherf (1993).

Species	Breeds	At risk
Cattle	783	112
Sheep	863	101
Goat	313	32
Pig	263	53
Buffalo	62	1
Horse	357	81
Ass	78	11
Total	2719	391

the diversity present in crops, however, is provided in Table 3.1-6, which lists the number of distinct samples of germplasm collected for major crops, ranging as high as 50 000 to 125 000 for maize, rice, barley and wheat. The magnitude of genetic diversity is also reflected in the substantial numbers of varieties grown in local regions. For example, Andean farmers cultivate thousands of different clones of potatoes, more than 1000 of which have different names. Table 3.1-7, adapted from Oldfield (1992), provides some information on the conservation status of wild relatives of major food crops, and their potential in breeding programmes. Little is known of their vulnerability, but in most cases habitat destruction is likely to be the principal threat. The organizations belonging to the Consultative Group on International Agricultural

Table 3.1-9: World-wide numbers of breeds of the common domestic species of mammals in each region. Figures derived from Loftus and Scherf (1993).

Region	Breeds	At risk
Western Europe	731	218
Former USSR	327	57
Asia	746	51
Africa	297	9
North and Central America	169	30
Latin America	165	23
Near East	284	3
Total	2719	391

Research (CGIAR) have active programmes to preserve at least some of this biodiversity (see Section 8.8.5 and Box .8-1.

The number of breeds at risk by species and by region is given in Tables 3.1-8 and 3.1-9, following Loftus and Scherf (1993), although different and generally rather higher figures are given by Hall and Ruane (1993; and see Section 2.2.2.1). In most instances breeds have not been tabulated exhaustively and the true totals are expected to be larger. The numbers of breeds ‘At risk’ in these tables are determined mainly by breed population size. ‘At risk’ includes two subcategories, which are broadly defined as ‘Critical’ if there are fewer than 100 animals and ‘Endangered’ if there are more than 100 but fewer than 1000. In the absence of population size data (these are currently available for only about one-third of the breeds in regions other than Western Europe and the former USSR) no breed is recorded as being ‘At risk’. Figures for many regions are therefore likely to be considerable under-estimates.

Breeds within a species can, of course, be used for crossbreeding. This ability is a potential source both of economic benefit and of genetic erosion. Using an economically superior breed to cross with a less productive indigenous breed can lead to relatively rapid increases in productivity by additive gene effects and also, in certain traits, by heterosis. Compared with trying to introduce a different species for improved livestock production, this crossing option is a tremendous advantage. The down-side is the increasing likelihood that the genetic variation as defined in the genotype of the indigenous breed may disappear quite rapidly.

This process of breed replacement by crossbreeding has occurred on a large scale in Western Europe during the three decades from 1960, with a resultant loss of domesticated biodiversity. Economically important breeds such as the Holstein-Friesian for milk, and the crossbred strains produced by specialist breeding companies for pigs and poultry for both egg and meat production, now dominate the animal production scene in Western Europe and North America. The same trend is slowly taking place in developing countries wherever environmental and management infrastructures permit the change. Thus, many of the original indigenous breeds of domestic livestock in Western Europe are now reduced to small populations. Mason and Crawford (1993) name 97 breeds of cattle, goats, horses, pigs and sheep in Europe which are extinct, and comparable serious losses of genetic diversity are indicated for other regions. The FAO Animal Genetic Resources Data Bank contains information on 198 extinct breeds in regions other than Western Europe, 106 of them in the former USSR (Loftus and Scherf 1993) (see Table 3.1-10).

A very large number of breeds were lost in the former USSR during the period of the command economy. In the

current transitional period 57 breeds remain at risk in the Russian Federation. These are in immediate need of conservation, even though this is unlikely to be easily funded or given high priority in a period of such economic stress. On the other hand, although a large number of breeds (97) have been lost in Western Europe in the thirty-year period 1950–1980, when the conservation of traditional breeds was not given serious attention, the relatively large number of breeds now classified as being at risk in Western Europe because of their small population sizes are nearly all the subject of some form of conservation programme, with live animals held in secured herds and/or semen or embryos stored in deep-freeze facilities.

All of the arguments about loss of biological diversity that are applied to wild species apply also to the loss of genetic diversity in domesticates, plus strong economic and social considerations. There is an obligation to conserve for future generations as much as possible of the biological diversity which has been inherited. The threat to domestic animal biodiversity results from unsustainable practices which, if continued without restriction, regulation or planned sustainability, will inevitably lead to increased depletion and loss of the natural resource base needed for future production. The transfer of unsustainable practices of animal production from the developed to the developing regions and to the countries of the former command economies will inevitably cause even further loss of domestic animal biodiversity unless conservation programmes are instituted and development becomes sustainable.

CENTRAL CHILE—SPECIES COLLECTED

Figure 3.2-1: Species richness surface for vascular plants interpolated from numbers of species occurring in 0.5×0.5 latitude grids in central Chile, based on herbarium records in the Chilean flora database. The foreground is the Pacific coast of Chile. The unevenness of the surface is partially a reflection of variation in the sampling intensity, with many areas undersampled to reveal their true species richness (Arroyo *et al.* unpublished data).

3.2 The distribution of biodiversity

3.2.0 Introduction

Discerning pattern is a fundamental aspect of research in the biological sciences. Knowledge of pattern leads to prediction, and prediction provides a basis for testing theory, and for taking action. This chapter assesses the current state of knowledge of patterns of biodiversity at the global, regional and local scales, and their correlates, and reviews current explanations for such patterns.

3.2.1 Geographical patterns of biodiversity

For reasons that are easily understood, most efforts to assess geographical patterns in diversity have considered species as the currency of biodiversity. Assessments of large-scale geographical patterns of diversity, in which phylogenetic distances between all species of an area are given weight, are wanting.

Total organismal biodiversity – that is, the sum of all species (or of any higher taxa below the level of phylum) of all organisms – has not been tabulated for any area of land or water at any scale. That is, we currently have no assessment of the total accumulated product of organic evolution and of the ecological processes that maintain diversity, for any single area of the planet, let alone the total accumulated phylogenetic diversity. This implies that we are a long way from being able to provide an objective assessment of the role of biodiversity in maintaining ecosystem processes, of being able to understand the total consequences of loss of biodiversity on atmospheric properties (see Section 6), and of being able to assess the total potential economic value of biodiversity for different regions (see Section 12).

While there are good estimates of total richness for some of the better-known taxonomic groups (e.g. birds, butterflies, vascular plants), little is known about large-scale spatial biodiversity patterns for many of the most diverse groups of organisms on Earth, for example eubacteria, nematodes, microfungi, and various groups of protozoa, algae and arthropods. Many species, as much as 40% in beetles (Stork 1995), are still known from only a single collection and/or locality. Even in better-known groups such as vascular plants, perceived variation in diversity at the spatial scales that are most useful for determining conservation priorities sometimes reflects sampling effort rather than true pattern (Figure 3.2-1). These many biases reflect the fact that we are still at the stage of learning about what species are present on the Earth, a stage that necessarily implies a taxonomic approach, and many short-cuts when it comes to exploration, rather than an eco-biogeographical one. Clearly, however, without access to sound taxonomy, it will be very difficult to reach this second stage.

Ecologically, sampling is often concentrated in the more ‘typical’ part of a community. This means that ecotones and key local environmental gradients are often neglected.

3.2.1.1 Gradients

The existence of gradients in diversity implies that diversity has accumulated differentially over evolutionary and ecological time from one location to another. For predictive purposes, a key question is whether such gradients are congruent, when all groups of organisms are considered together.

Natural historians have pondered large-scale gradients in species richness for nearly two centuries, since Humboldt

Figure 3.2-2: Relationship between tree species diversity in small forest plots and the actual annual evapotranspiration, which is proportional to ecosystem productivity (from Latham and Ricklefs 1993b).

commented on the temperate–tropical disparity in tree species richness (Humboldt and Bonpland 1807; cf. Carlquist 1974; MacArthur and Wilson 1967; May 1975b). Then, as now, most accounts have focused primarily on particular taxonomic groups (e.g. birds, beetles) or functionally or morphologically similar organisms (e.g. trees, marine and freshwater plankton).

3.2.1.1.1 Terrestrial environments. A trend of increasing biodiversity with decreasing latitude applies across many groups of organisms (Fischer 1960; Stevens 1989) on land. Stated simply, more species (or higher taxa) in these groups live in a given area in the tropics than in similar-sized areas at higher latitudes. This pattern has been attributed to such groups as trees (Latham and Ricklefs 1993a), mammals (Simpson 1964), birds (Cook 1969), reptiles and amphibians (Kiestler 1971) and insects (Stork 1988), among others.

No one seriously suggests that latitude *per se* drives biodiversity gradients but several factors that might influence biodiversity at various scales co-vary with latitude. Total land area decreases with increasing latitude (Terborgh 1973; Osman and Whitlatch 1978; Rosenzweig and Abramsky 1993), although patterns differ between the hemispheres. Other potentially important factors include temperature, total precipitation, seasonal variation in precipitation, and ecosystem energy flux.

In some major groups, however, the distribution of biodiversity exhibits no strong relationship with latitude, or even increases to a maximum in temperate zones. For example, only slightly more species of polypore fungi have been recorded in the entire continent of Africa (360) than in the much smaller and ecologically less diverse area of Europe (330), in contrast to a plant species ratio of about 10:1 (Ryvarden 1993). For well-sampled freshwater zooplankton, Cladocera show no trend with latitude while Rotifers increase in diversity towards the tropics (Dumont

1994, Segers *et al.* 1992). A ‘humped’ pattern, with highest diversity at mid-temperate latitudes, is exhibited by ichneumonid wasps (Janzen 1981; Hawkins 1990), psyllids or jumping plant lice (Eastop 1978), and aphids (Dixon *et al.* 1987; Price 1991).

Vascular plants in Africa show a major increase in diversity southwards from tropical to temperate latitudes (Gibbs Russell 1987). Local species diversities of herbaceous plants are as high in the temperate prairies of central North America as in tropical grasslands (Ricklefs 1977a). A striking example, although of a different nature, is provided by the 28 species of vascular plant epiphytes documented as occurring on a single tree in New Zealand, exceeding anything reported for the tropics to date (Dickinson *et al.* 1993).

Where latitudinal gradients have been examined closely, the relationship with biodiversity has often turned out to be complex, as discussed by Holloway (1987) for butterflies in the Indo-Australian tropics. In a compilation of tree species richness data from broad-leaved forests from 106 tropical and 22 temperate sample areas of 0.5–10 ha, representing 30 and 16 locations respectively (Latham and Ricklefs 1993a), species richness varied with latitude, but not linearly (Figure 3.2-2). Tropical samples had higher species richness than temperate samples, but species richness was independent of latitude within the temperate and tropical groups of samples. In some groups that reportedly show no pattern in diversity with respect to latitude, it is not always clear to what degree this might be an artefact of sampling effort.

In some groups of organisms, latitudinal patterns are expressed differently north and south of the Equator. For example, total tree species diversity falls off much more steeply from equatorial regions into the southern temperate zone than it does to the north. This is attributed to the far smaller extent of the southern temperate forested areas in South Africa, Australia and southern South America, compared with their northern counterparts in Europe, eastern Asia and North America (Currie 1991). However, a recent and perhaps more meaningful comparison of plant diversity in the rain forests of the Pacific Northwest of North America and southern South America, two climatically similar areas, showed that while there is a steeper latitudinal gradient in species richness in southern South America, overall the forests in southern South America are richer (Arroyo *et al.* 1995b).

Biodiversity differences among continents and hemispheres can sometimes easily be explained by reference to corresponding differences in such factors as climate and landscape heterogeneity. More often than not, however, they cannot be explained in this way. Greater climatic equitability in southern South America in comparison with the west coast of North America, allowing retention of more older Tertiary groups, is cited as a

potential factor contributing to hemispheric differences in plant diversity in rain forest floras (Arroyo *et al.* 1995b) and bird diversity at the species, genus and family levels (Jaksic and Feinsinger 1991). However, it is not immediately obvious why New Zealand, with a land area of only around 3% that of the continental United States, may have as many species of spiders (estimated 3600 species): predominantly temperate Australia has more than twice that number (estimated 9300 species; Platnick 1992). Mangrove species, genera and families are several times more diverse in the Indo–West Pacific region than in the Atlantic–Caribbean–East Pacific (Ricklefs and Latham 1993). The three large temperate forest areas – east-central Asia, eastern North America, and Europe – have an overall tree species richness ratio of 6:2:1, with parallel differences at the genus, family and order levels (Latham and Ricklefs 1993b).

For several groups of terrestrial organisms, diversity has been found to decrease with increasing altitude (Stevens 1992). Examples include bird species in New Guinea (Kikkawa and Williams 1971, cited in Brown 1988) and on the eastern slope of the Andes in Peru (Terborgh 1977), woody plant species in tropical forests (Gentry 1988), and amphibians in the Western Ghats in India (Daniels 1992).

Humped patterns of diversity on elevational gradients, with diversity lower near the foot and the summit and higher at mid-slope are known in particular groups and in some geographical areas. Examples span a wide range of taxa including flowering plants on the western slopes of the Andes in northern Chile (Arroyo *et al.* 1988), birds in the Mediterranean climate zone of California (Cody 1975), and large moths in northern Sulawesi and the Moluccas (Holloway and Stork 1991). In Chile, the diversity of vertebrates increases with altitude from the Pacific coastal desert up to the high Andean plateau, indicating the influence of local environmental conditions on diversity–altitude relationships (Pearson and Ralph 1978).

Several factors parallel to those seen with latitude might impinge directly on the processes influencing diversity on elevational gradients. Land area decreases with increasing elevation. Temperature and energy flux also are inversely correlated with elevation. In addition, stresses such as wind, ultraviolet radiation from the Sun, and daily temperature variation co-vary positively with elevation.

Diversity of many taxa decreases along the length of peninsulas, such as the Florida Peninsula and Baja California (Simpson 1964; Cook 1969; Seib 1980; Brown 1987; Case and Cody 1987). Diversity at many taxonomic levels also tends to decrease from continents to islands or within continental areas with increasing distance from potential sources of colonists (cf. MacArthur and Wilson 1967). Among large continental areas, the Mediterranean-type climate area of Chile is strongly isolated by the Pacific Ocean to the west, the Atacama Desert to the north, the

Figure 3.2-3: Diversity of animal phyla in different habitats. Marine habitats harbour both more phyla and a larger proportion of endemic phyla than other habitats (after Ray and Grassle 1991).

Andes mountains to the east, and austral rain forest to the south, and thus is biogeographically similar to an island. Compared to the California region, which has a very similar climate, Chile supports fewer species of birds (Cody 1975) and fewer species and genera of vascular plants (Arroyo *et al.* 1995a). The diversity of lizards in Chile is comparable to that in California, but comprises the radiation of a single genus *Liolaemus* (Fuentes 1976). Another area where isolation has been important, in this case for birds, is the Western Ghats in India (Daniels *et al.* 1992).

In summary, for terrestrial environments, although there are general trends for increasing species diversity towards the tropics in many large taxa, and also along elevational gradients, the numerous exceptions and incongruities among groups should caution us against generalizing and focusing the attention of conservation efforts predominantly in the tropics (e.g. Mares 1992; Baskin 1994) and at lower elevations. The examples quoted above show that general trends with latitude or elevation are unlikely to be strongly predictive, and that local knowledge of biodiversity will always be necessary. Better knowledge of soil-dwelling organisms is particularly critical for providing a better assessment of latitudinal and altitudinal gradients.

3.2.1.1.2 Marine environments. Although the oceans cover 71% of the Earth’s surface, named terrestrial species outnumber those in marine environments by seven to one (Lasserre 1992; May 1994). It is unknown to what degree this proportion is influenced by sampling bias. Quite simply, we know the land better than we know the sea. At a local scale, the richest marine ecosystems, such as coral reefs, may have levels of species diversity roughly similar to the richest terrestrial ecosystems (for example, lowland tropical rain forests), if the small fraction of taxa thoroughly inventoried to date in these systems reliably indicates the species totals.

At the phylum level, marine diversity is close to twice that of the land (Figure 3.2-3). Of the 33 extant phyla of animals (Margulis and Schwartz 1988), 32 occur in the sea, 15 are exclusively marine, and five are nearly so. In contrast, only one phylum is endemic to the land (Figure 3.2-3). The functional role played by this phylogenetic diversity is virtually ignored (Grassle *et al.* 1991; Lasserre 1992). Of course, the groups that are recognized as phyla in our existing classifications are not necessarily equivalent in age. Comparisons at this higher taxonomic level should be viewed with caution until better knowledge of the relationships among marine non-vertebrates becomes available. Further research is clearly needed to assess the relative amount of phylogenetic diversity in the oceans in relation to the land.

Large-scale pattern in diversity is probably even less clear in the sea than on land. A latitudinal gradient is evident in some fossil groups, for example, Cretaceous foraminifera and Permian brachiopods (Stehli *et al.* 1969). For present-day groups, an increase in diversity with decreasing latitude has been described for marine molluscs (Stehli *et al.* 1967). Studies of deep-water benthic invertebrates have shown consistently high species diversities across latitudes (Grassle 1989, 1991; Grassle and Maciolek 1992), although a recent study has described a latitudinal gradient of increasing diversity toward the tropics (Rex *et al.* 1993). Counts of pelagic marine plankton species in five-degree squares throughout the world's oceans (Reid *et al.* 1978; McGowan and Walker 1993) attest to the complexity of the sea. These studies show lowest diversity at high latitudes, highest diversity at middle latitudes, and intermediate diversity within 15° of the Equator, with a sharp discontinuity between highest and lowest levels at 40° to 42° latitude in the northern hemisphere and a smoother, more gradual transition in the southern hemisphere.

A humped latitudinal diversity pattern is evident in macro-algae (seaweed) communities, the most diverse of which are found in temperate nearshore areas (Lasserre 1992). A parallel and probably closely related pattern is displayed by the nearshore shallow bottom fauna (Thorson 1957), although a study of macro-invertebrates in nearshore soft-bottom marine communities in Java and Great Britain (Warwick and Ruswahyuni 1987) revealed no difference in species diversity between sites. Marine algae show an increase in diversity along the coast of Chile from 17° S southward (Santelices 1989).

Marine biodiversity generally decreases with increasing depth. Some shallow-water marine invertebrate communities are among the most biologically diverse assemblages known. However, gastropods exhibit a humped diversity curve with depth, peaking in moderately shallow waters (Rex 1981). Recent inventory work on the deep-sea floor in the North Atlantic (Grassle 1991) and southwest Australia (Poore 1993) has considerably

complicated the interpretation of the depth–diversity relationship. Using relatively new technology, this work indicates a previously unimagined richness of species and higher taxa, rivalling that of coral reefs.

No strong evidence has yet emerged in the marine realm for differences in biodiversity patterns between the northern and southern hemispheres. Less evidence of concentration of richness in the tropics in the marine realm compared to the land, coupled with clear incongruence among groups, emphasizes that future research efforts in the sea must span all latitudes.

Such research is particularly needed as coastal marine environments, ecotones stretching from the land to the sea, are especially affected by human activities, and conservation measures are urgently required (e.g. McNeill and Fairweather 1993; Sherman 1994), as discussed in Section 13.

3.2.1.2 Centres of diversity

Broad geographical gradients in diversity can be overlain with specific centres of diversity. For example, within tropical forest Myers (1988) identified ten areas, comprising 3.5% of the remaining primary forest, that harbor an estimated 34 400 endemic plant species and 27% of all tropical forest species of plants (but see Myers 1990 for a broader analysis). Vane-Wright *et al.* (1991) mapped diversity for a number of groups in an attempt to identify prime areas of conservation concern. In practice, the definition of centres of diversity is not easy, due to scale problems and choice of taxonomic group (Mares 1992).

Knowledge of where such centres are located becomes very important in selecting options between preservation and the sustainable use of biodiversity. The probability of sustainably managing species-rich areas for a given resource, and of adaptive management, should be lower than for species-poor areas, given the lesser complexity of the latter, and the greater speed with which relevant ecological knowledge on all species present can be obtained and incorporated into harvesting and management plans. Again, a key question is whether centres of diversity are congruent across different taxonomic groups. The relationship between centres of diversity and centres of endemism is discussed in 3.2.1.2.4 and 3.3.4.1.

3.2.1.2.1 What is a centre of diversity? In its simplest definition, this is merely an area with a high number of species. Centres of diversity may be recognized on global, regional and local scales. Each scale has a particular relevance on its own, and information at the finer levels of resolution is clearly essential for completing the broader global surveys. The choice of recognizing centres of diversity on a habitat versus area basis will depend on the particular purpose (e.g. conservation of a particular taxon, versus detection of the most appropriate area to optimize a general conservation effort). In identifying global and regional centres of diversity for any one habitat type, a

centre of diversity constitutes a positive deviation from the relationship of diversity to various environmental predictor variables, within that habitat type. That is, centres contain more species, or more of some other measure of biodiversity (e.g. number of phylogenetic lineages), than would be expected on average from their physical characteristics (such as temperature, precipitation regimes and soil qualities).

Within a given country, by contrast, a centre of diversity will often represent an area of high species richness that may or may not be of great significance regionally or globally. Usage of the centre of diversity concept in this last context should not be discouraged, as the detection of local centres of richness is essential for the elucidation of regional and global patterns.

The circumscription of a true centre of diversity requires, above all, adequate exploration and sampling. Without the latter, the risk is run of confounding an area of more intensive collecting with a true centre of diversity (see Figure 3.2-1). This will be particularly true when dealing with generally species-rich, or inconspicuous, groups of organisms (e.g. fungi). When the scale is global or regional the task is less daunting, due to the fact that the probability of picking up individual species will increase as the area considered increases.

Reliable analyses of centres of diversity at all three scales are effectively just beginning (Williams and Humphries 1994). On a global scale, the IUCN Plant Conservation Office (IUCN 1987; Davis *et al.* 1994–5) has identified 234 areas of especially high plant species diversity, concentrated in northwestern South America, Central America, tropical Africa, the eastern Mediterranean region and Southeast Asia/Malesia. The sites selected had to meet one or both of the following criteria:

- the area is evidently rich in species, even though the number of species present may not be accurately known;
- the area is known to contain a large number of endemics.

In addition, the following characteristics were also considered when making the selection:

- the site contains an important gene pool of plants that are of value to humans or that are potentially useful;
- the site contains a diverse range of habitat types;
- the site contains a significant proportion of species adapted to special edaphic conditions;
- the site is threatened or under imminent threat of large-scale devastation.

Sites of importance for the maintenance of avian biodiversity are being detected and described on a regional basis by BirdLife International [formerly International Council for Bird Preservation, ICBP] (Bibby *et al.* 1992). Most of these analyses are based on the numbers of restricted taxa recorded within latitude–longitude blocks and therefore do not control for within-block habitat heterogeneity or distinguish within- and between-habitat components of diversity. Thus, while global surveys have been identified for some areas of potential conservation interest, further spatial and ecological resolution within these areas is badly needed (e.g. Crowe and Brooke 1993). At a regional level, Maldonado *et al.* (1995) have used species-accumulation curves to determine whether floristic knowledge is sufficiently reliable to detect overall richness in the Compositae in central Chile at different scales, and this kind of analysis is now being extended to the entire Mediterranean flora, and for progressively smaller geographical areas, in order to detect local areas of diversity.

On a regional scale, centres of diversity are likely to be related to particular habitat types, typically the most productive or structurally complex. For example, the subtropical *pantanal* marshes of the Paraguay River in South America support an enormous diversity of mammals. These marshes are seasonally flooded, and because the prevailing soils are sandy, a complex mosaic of xerophytic and mesophytic vegetation occurs there. Although none of the mammal species is endemic to the *pantanal*, the interdigitation of xeric and mesic vegetation and of terrestrial and aquatic habitats results in a rich mammalian fauna, even richer than that of more typical tropical areas (Alho and Lacher 1991).

In some cases, regional centres of high species richness have been shown to contain large numbers of closely related species. For example, the *fynbos* habitat of the Cape Floristic Region of southern Africa has 526 species of *Erica* (Cowling 1992), at least some of which have probably proliferated fairly recently owing to special conditions (fire) that promote occasional isolation of subpopulations of plants having certain non-fire-tolerant characteristics in their life–history (Cowling and Holmes 1992). Cyclic creation and rejoining of forest refugia within Australia has similarly resulted in many speciose genera of birds (Keast 1961; Cracraft 1985b) and plants (600 species of *Eucalyptus*; Groves 1994).

On a local scale, within a particular habitat type, variation in species diversity will likely reflect factors such as history of land use or natural disturbance. Frequently, areas protected from natural disturbance cycles, such as those associated with fire, will experience a decline in diversity owing to the loss of species typical of the early successional stages (Connell 1978). Diversity may also be locally sensitive to exposure or vulnerability to natural

disturbances, creating differences between windward and leeward sides of mountains (Smith 1972), and between sites with different slopes or exposure to wave action (Lewis 1964).

The value of the centre of diversity concept could be greatly strengthened by ranking the functional roles of the species concerned, and assessing their phylogenetic status (see Section 2.1). For example, the relative diversity content of the temperate rain forest of southern South America, with many monotypic, endemic genera, one endemic family and a wide spectrum of woody life forms (Arroyo *et al.* 1995b) could turn out to be much higher than that of adjacent more speciose areas of Mediterranean-climate area to its north in Chile.

3.2.1.2.2 Do centres of diversity share general features?

On a global scale, centres of diversity often appear to occupy areas of rapid habitat transition and therefore high ecological heterogeneity. For terrestrial plants, these tend to be mountainous regions, such as the Andes; areas dominated by coastlines (Central America, the Mediterranean, Malesia), as mapped in Davis *et al.* (1994) and/or regions of high tectonic activity. A similar pattern appears with regard to centres of diversity identified by the International Council for Bird Preservation (Bibby *et al.* 1992) among endemic birds – those having restricted ranges (< 50 000 km²). These tend to cluster in mountainous regions, including the Andes, and on islands, especially those of Malesia and Polynesia.

Locally, species numbers can be augmented by the mixing of previously isolated biotas, as occurred following the completion of the land bridge between North and South America (Darlington 1957; Webb 1991), and the opening of the Suez Canal between the Red Sea and Mediterranean Sea (e.g. Vermeij 1991). Some authors have argued that some areas of high species diversity, including the diverse marine communities of the western Indo-Pacific (reef-building corals and fish assemblages, for example), represent the accumulation of taxa produced peripherally, and which persist owing to low extinction rates within the area (McCoy and Heck 1976; Jokiel and Martinelli 1992; Pandolfi 1992). This scenario has been inferred from the occurrence of many young taxa within centres of diversity, with older (more basal) taxa at the periphery. In most cases, however, centres of diversity also include basal taxa and most likely represent the initial centres of diversification.

3.2.1.2.3 Are centres of diversity for different taxa congruent? The majority of vascular plant species are tropical in distribution (Ricklefs and Renner 1994). However, a good number of plant families are found only in temperate latitudes. For these, centres of diversity clearly are not congruent with the majority of other plant families. Other large taxa, such as ichneumonid wasps and scolopacine shorebirds (during the breeding season),

have their centres of diversity beyond the tropics, and in the case of the scolopacines, at high latitude. Thus on a global scale, centres of diversity across taxa are not necessarily congruent. At a regional scale, congruence characterizes some groups, but not others (e.g. Bibby *et al.* 1992). On a finer geographical scale, centres of diversity have generally failed to find show close congruence across all groups owing to the variation in the habitat requirements and mechanisms of species production in different groups (Bibby *et al.* 1992; Prendergast *et al.* 1993). Schall and Pianka (1978) and Pianka and Schall (1981) tabulated numbers of species in several groups of vertebrates in 240 × 240 km grid squares in Australia. Most pairs of these groups exhibited negative correlations in diversity, suggesting the groups had different responses to environmental variables. Similar absence of correspondence between the diversities of different groups has been noted in South American plants (Gentry 1992).

Within a given habitat type, mangrove forests of Southeast Asia support six times the number of species of mangroves regionally, and two to three times the number of mangrove species locally, as mangrove forests in the Caribbean Basin (Tomlinson 1986; Duke 1993; Ricklefs and Latham 1993). Furthermore, the Caribbean mangroves contain only two genera of trees, both monotypic (*Laguncularia* and *Pelliciera*), not found in the Indo-Pacific region. Thus finding high species richness in a particular habitat type will not necessarily mean that all areas of that habitat type are equally rich.

3.2.1.2.4 Do centres of diversity correspond to areas of endemism? The degree of endemism (see 3.3) in local biotas is arguably as important as their overall diversity. It is therefore relevant to determine whether centres of diversity and endemism correspond. Diversity *per se* and endemism are produced by somewhat different processes such that correspondence between centres of diversity and endemism will not always be expected. While endemism is the product of isolation, build-up of local biotas requires both isolation to allow genetic differentiation between populations and exchange of populations between semi-isolated areas to bring newly allopatrically formed species back into sympatry (see Section 4.3; Patton and Smith 1992; Arctander and Fjeldsa 1994). Thus, remote islands may frequently harbour distinctive endemics, but rarely large numbers of species. By contrast, individual islands within archipelagos frequently accumulate larger numbers of species through exchange and further differentiation. When areas of suitable habitat are close, the migration of individuals among them prevents differentiation and thus fosters neither endemism nor the build-up of species.

On continents, isolation can be effected as new biomes or vegetation types appear over time, as occurs in the case of the highly endemic southern South American rain forest,

which is now completely isolated from other neotropical wet forest areas by arid vegetation types in the interior of the continent (Arroyo *et al.* 1992, 1995b). Very striking cases of combined high species richness and endemism are the Mediterranean-type climate floras (e.g. Raven and Axelrod 1978; Cowling *et al.* 1992; Arroyo *et al.* 1995a). More locally, in Lake Baikal, for the benthos and littoral, ancient endemics in some groups coexist with speciose groups in others (Brooks 1950; Martens *et al.* 1994).

3.2.1.3 Introduced species

An organism that has colonized an area outside its normal range with human assistance, intentional or unintentional, is said to be introduced (alien, exotic). Invading species of plants are generally fast-growing, and compete aggressively for local resources. High reproductive output and adaptations for long-distance dispersal (Baker and Stebbins 1965; MacArthur 1972; O'Connor 1986; Drake *et al.* 1989; Groves and di Castri 1991) are features that are typically correlated in such species.

The diversity of introduced organisms is especially high in some areas with long histories of overseas human interchange and commerce (Long 1981; Crosby 1986; Drake *et al.* 1989; Fox 1990, 1995; Beardsley 1991; Lodge 1993). An additional predictable characteristic of invaded places is a lack of appropriate 'natural enemies' – predators, parasites and diseases – to control the introduced organism. For example, the Mesoamerican legume *Mimosa pigra* is attacked by five species of pathogenic fungi in Mexico, but has become an invasive weed in Australia and Southeast Asia where the pathogens are absent (Evans *et al.* 1993). Areas with a history of isolation, such as islands in general (Elton 1958; Diamond 1984; van Riper *et al.* 1986; Webb *et al.* 1988; Wagner *et al.* 1990) and the South American continent (Groves and di Castri 1991; Vermeij 1991), seem to be more vulnerable to invasion. The large introduced floras of biogeographically isolated Chile (Marticorena 1990) and California (Hickman 1993), with long histories of overseas exchange and severe vegetation degradation (e.g. Fuentes and Muñoz 1995), situated on the relatively easily invaded South American continent in the case of Chile (Groves and di Castri 1991), provide striking examples of the interaction of key factors promoting susceptibility to invasion.

Regionally, introduced biodiversity tends to lead to increases in overall biodiversity. However, locally the effect can be just the opposite. Many introduced species tend to be restricted to disturbed habitats or habitats created by humans (Herbold and Moyle 1986). While adding to overall species diversity, their presence signifies commensurate reductions in population size in other native species, through habitat preemption. Examples include the European starling, *Sturnus vulgaris* (Elton 1958), many herbaceous plants in the *fynbos* of southern Africa

(Richardson *et al.* 1992) and in the steppe zone of Tierra del Fuego (Moore 1983), and cichlid fish in Lake Gatun (Zaret and Paine 1973). Others are capable of invading relatively undisturbed ecosystems. Examples include *Myrica* in Hawaii (Vitousek *et al.* 1993; Ludyanskiy *et al.* 1993), the brown tree snake in Guam (Savidge 1987; McCoid 1991) and *Poa* spp. in the remote deciduous *Nothofagus* forests of southern South America (Moore 1983). In these cases, reductions in the local population size of native species can be expected to be even more severe. A pattern that can be expected to become more common in the future is for alien species to find their way further into undisturbed habitats, with resultant local population differentiation and eventual speciation. Introduced species or cultivated varieties pose threats not only to natural communities, but also to the ecological sustainability of harvesting and cropping systems, by competing for nutrients or ousting key native species (Diamond and Veitch 1981; Kitching and Jones 1981; Courtenay and Stauffer 1984; Mooney and Drake 1986; Culotta 1991; Jaksic and Fuentes 1991; Kaufman 1992).

3.2.1.4 Domesticated species

Nearly every human culture has domesticated animals and plants (see Section 4.1.4) and the distribution of domestic organisms broadly follows patterns of present human settlement (Crosby 1986).

Centres of origin of domestic biodiversity can be correlated with ancient centres of human culture in Africa, Asia and South and Central America (Heiser 1973; Hawkes 1983; Clark and Brandt 1984; Purseglove 1972; Hemmer 1990). Herbaceous crop species are often descended from weeds, and like many weeds may be less dependent than other plants on mycorrhizal fungi and more responsive to inorganic fertilizer inputs (Chapin 1980; Chapin *et al.* 1986; Safir 1987), in some cases because they have been selected for responsiveness to fertilizer (Jasper *et al.* 1979). Crops of the future are likely to come from the warm tropics and from arid environments, areas where there are needs and the most glaring gaps in our current crop repertoire.

Most ornamental plants do not present threats to biodiversity, except in that they occupy space that might otherwise support natives (Simberloff 1981; but see Herbold and Moyle 1986) but a number of them have escaped from cultivation and become weeds or invasives.

3.2.1.5 Rarity

Rarity is a topic of both scientific and popular concern and the subject of considerable confusion in the literature. Rabinowitz (1981) categorized plant species according to geographical range (large or small), local population size (large or small) and habitat specificity (wide or narrow). Of the eight possible combinations of these states, she

recognized seven as constituting different forms of rarity. The eighth group (common species) have large populations and ranges, and wide specificities (see also discussion in Gaston 1994). It goes without saying that the detection of rarity depends upon adequate sampling, and that sampling gaps can lead to the overestimation of rarity. Several surveys have described the general spectrum of distribution of species in these forms of rarity – for example, plants of the British Isles (Rabinowitz *et al.* 1986), birds of Central America (Karr 1977) and plants of Australia (McIntyre 1992). Typically, all possibilities are represented. Fiedler (1986; Fiedler and Ahouse 1992) proposed a list of factors as necessary and sufficient to the understanding of the causes of rarity in vascular plant species. Very valuable basic surveys of rare species have been conducted by IUCN and WCMC (see WCMC 1992). Greuter (1991) estimated rarity for the flora of the entire Mediterranean basin based on collection data and frequency of occurrence in Med-Checklist areas, and found that 48% of all species occur in a single Med-Checklist area. Here we focus on geographical and ecological correlates of the three rarity components.

There have been few attempts to discern pattern in the size of geographical range (but see Rapoport 1982). Based on the latitudinal distributions of several taxa in North America, Stevens (1989) proposed that latitudinal extent of distribution decreased on average towards the Equator (Rapoport's rule). In South America, a similar trend has been documented for tree species in the temperate rain forest zone (Arroyo *et al.* 1995b). Stevens (1989) developed a model based on high habitat specialization in the tropics, combined with movement of individuals between habitats (mass effect), to explain part of the high biodiversity of the tropics. Unfortunately, Stevens's data set did not extend into the tropics, where geographical distributions of many taxa are poorly known, or for which data are not readily accessible. However, Rohde *et al.* (1993), in a global analysis of the distribution of marine teleosts, found that latitudinal ranges were greater in the tropics compared to higher latitudes, although diversity is highest within the tropics. Although it is clear that taxa with both broad and narrow distributions occur in both the tropics and high latitudes, it is premature to draw general conclusions concerning this issue (Rex *et al.* 1993; Colwell and Hurltt 1994). Clearly, range size should be investigated systematically among a variety of key taxa, controlling carefully for confounding factors, such as variation in elevation which can provide extended habitats for the distribution of cold-loving taxa (Arroyo *et al.* 1995b).

With respect to habitat specialization, the information is inadequate. The few comparative studies available show increasing habitat or host-plant specialization with increasing diversity of species (e.g. Scriber 1973; Cox and Ricklefs 1977). Janzen (1967) proposed that high-latitude

terrestrial taxa have broad habitat distributions because they must be capable of tolerating seasonal variation in the environment, which in turn enables them to live in a variety of habitats (see also Stevens 1989). Effectively, the less seasonal environments of the tropics, particularly with regard to temperature, allow for specialization and greater zonation with respect to elevation. Thus, as Janzen points out, mountain passes appear to be 'higher' in the tropics, imposing greater barriers to dispersal and increased opportunity for allopatric speciation.

With respect to local abundance, given similar total numbers of individuals in two areas, species in the area of higher diversity will tend to be less abundant on average (Coddington *et al.* 1991). Forest tree species, which can be counted individually on a per-hectare basis, are locally less abundant on average on more diverse sites. It is undoubtedly true that diverse assemblages, as in the tropics, will tend to have more locally rare species than depauperate assemblages; however, this does not mean to say that depauperate assemblages do not harbour any rare species.

Small islands constitute another habitat in which total population rareness can be expected as a result of the limited area of suitable habitat. Analyses of the distributions of birds in the West Indies (Ricklefs and Cox 1972; Cox and Ricklefs 1977) indicated that rare and endemic species frequently occupied habitats of small geographical extent (e.g. cloud forest, marshes) which differed ecologically from the more common habitats.

In view of the diversity of organisms and their biologies, it would be hazardous at this stage to draw general conclusions as to whether rare species share life history or other biological attributes. However, it is clear that widely distributed plants and cosmopolitan mould fungi produce relatively great numbers of seeds and conidia respectively. In the case of widely distributed plants, genetic self-compatibility and autogamy can be common, whereas in animals parthenogenesis is a correlate of widely distributed species (Cuellar 1994). As a corollary, species with the most limited capabilities of dispersal can be expected to colonize new habitats less easily and only recolonize ones from which they have been eliminated. Some such organisms have potential as bioindicators of habitat disturbance (Bates and Farmer 1992; Hawksworth 1993).

Rarity can signify vulnerability, although it is not a prerequisite: witness the great auk, passenger pigeon and Carolina parakeet (WCMC 1992). The extinct populations of Caribbean birds are drawn primarily from the old single-island endemics that tended to be more narrowly distributed ecologically and occurred at low densities within habitats (Ricklefs and Cox 1972, 1978). When either relic species or newly evolving neo-endemics are involved, rarity can also be related to endemism (see 3.3), one of seven rarity categories recognized in plants in the British Isles by Rabinowitz *et*

Figure 3.2-4: The number of species of flowering plants recorded in floras of areas of different sizes from all parts of the world. The horizontal ordinate shows the area concerned on a log scale ranging from 1 cm² on the left to the total area of the world on the right. The vertical scale, also on a log scale, is the number of species recorded in each particular area (from Williams, C.B. 1964. Figure 38, p. 94). For key, see overleaf.

(Figure 3.2-4 cont.)

al. (1986). In the case of mutualists, pests and pathogens, vulnerability will inevitably be linked to that of the host species. The richest localities within the range of a host plant, for fungi and arthropods restricted to them, are where that species is native and longest established, a phenomenon well known to seeking potential biocontrol agents (Waage 1991).

3.2.1.6 Diversity and scale

The effect on pattern of measuring diversity at different scales (see Section 2.3) should not be overlooked and can be illustrated by examples. Until fairly recently, the debate on the original causes and mechanisms maintaining diversity has been complicated because patterns manifested on different spatial scales have been mixed (e.g. Rice and Westoby 1983). Williams (1964) compiled a large set of data on local and regional floras from all continents from plots ranging in size from 10 cm² to the total terrestrial surface of the Earth (Figure 3.2-4). Some of the data sets, particularly the tropical ones, need to be revised (cf. WCMC 1992), but the general trends shown in this figure nonetheless hold.

The species–area continuum can be divided roughly into three parts. The first ranges from about 1 cm² to 1 ha (10 000 m²). Diversity on this scale is set by the sizes of the organisms (whether herbs or adult trees, for instance) and their spacing. Increases in diversity up to one hectare mainly reflect sample size (in addition to some degree of environmental heterogeneity).

From 10 ha (0.1 km²) up to 10 million km², plant richness increases steadily with area. At this scale, a greater variety of ecological conditions is included and therefore more sets of differently adapted species are added with increasing area. At the third – global – scale, continental floras are combined to make up the total terrestrial diversity. The latter is higher than that obtained from extrapolating from intracontinental diversity, showing the effect of distinct evolutionary histories among continents.

The generally higher diversity in tropical communities than in temperate communities needs to be examined at

different spatial scales. Gentry (1988) shows the species richness of plants in 0.1 ha (1000 m²) plots from 74 sites on different continents and at different latitudes. Local (alpha) diversity (Section 2.3.2, Box 2.3-1) is much higher in most tropical sites than in subtropical and temperate sites. Equatorial plots show a fivefold range in richness, from about 50 species to more than 250 in response to local climate and soil conditions. However, dissimilarity among nearby samples can also be very high in the tropics: beta diversity (Section 2.3.2, Box 2.3-1) is as important as alpha diversity in establishing the higher overall diversity of tropical plant communities.

3.2.2 Biodiversity patterns: correlates and explanations

3.2.2.1 Environmental factors and biodiversity

3.2.2.1.1 Climate and productivity. Terrestrial biodiversity can correlate with measures of precipitation and temperature (Richerson and Lum 1980; Brown and Gibson 1983; Turner *et al.* 1988; Wright *et al.* 1993). Exactly how it is correlated depends on the taxa and ecosystem concerned. For example, lizard richness declines with increasing mean annual precipitation in arid and semi-arid areas of North America north of Mexico (Scheibe 1987), while rodent diversity increases with precipitation in the same region and in Chile (Brown 1973; Meserve and Glanz 1978; Brown and Gibson 1983). In less arid areas, as in Texas, rodent diversities decline with increasing precipitation (Owen 1988). Hump-shaped patterns are sometimes seen when diversity is graphed against climatic variables (Begon *et al.* 1990; Rosenzweig and Abramsky 1993), when diversity is maximal at some intermediate point along the environmental gradient.

Integrated climate variables, such as potential evapotranspiration (PE or PET) and actual evapotranspiration (AET), have recently gained attention as correlates of terrestrial biodiversity. PE is essentially a measure of total heat flux, and AET is an estimate of how much of the existing precipitation would be evaporated or transpired from a standard 'sward' of grass on a standard soil (Major

Figure 3.2-5: Relationships between number of species of rodents and productivity or precipitation, which provides an index to productivity in dry areas. (a) the Middle East; (b) Chile and the southwestern United States; (c) Texas (from Rosenzweig and Abramsky 1993; figures from Ricklefs and Schluter 1993, Fig. 5.2, p.53, and Fig. 5.6, p. 54).

1963; Stephenson 1990). AET is not measured directly but is calculated from precipitation and temperature data using a complex formula. It correlates with primary productivity in terrestrial ecosystems (Rosenzweig 1968; Lieth 1975; Box 1978).

The relationship of diversity to PE or AET depends on the group studied, and may be increasing, decreasing or humped (Wright 1983, 1990; Currie and Paquin 1987; Owen 1988; Adams and Woodward 1989; Currie 1991; Rosenzweig and Abramsky 1993) (Figure 3.2-5). Studies of these factors and biodiversity has mostly been limited to terrestrial vertebrates and higher plants. In some cases trends are similar on different continents (Adams and Woodward 1989); in others a difference in diversity persists among continents after the effect of PE or AET is estimated (Latham and Ricklefs 1993a). The relationship appears to vary with the scale examined, with a tendency for diversity to increase monotonically with increasing PE and AET at larger spatial scales and when larger taxonomic groupings are considered (Currie 1991; Wright *et al.* 1993).

3.2.2.1.2 Environmental chemistry. Chemical characteristics of waters, soils and air are known to affect diversity. The effects of certain air pollutants, especially sulphur dioxide, on the reduction in diversity of lichenized fungi, bryophytes, associated invertebrates, leaf-dwelling yeasts and certain plant pathogens have been well documented (e.g. Ferry *et al.* 1973; Bates and Farmer 1992; Richardson 1992). Acid or nitrogen from polluted air has been linked to reduced diversity of mycorrhizal mushrooms in European forests (Jaenike 1991; Arnolds and Jansen 1992), and may have particular effects on cyanobacteria-containing lichens (Gilbert 1986). In aquatic habitats, such variables as pH, salinity, oxygen and nutrient concentrations are important. Nutrient concentrations, pH and cation exchange capacity are factors in soils. In both water and soil, experimental evidence shows declines in

diversity in artificially fertilized ecosystems (Tilman 1982; Goldberg and Miller 1990; Schindler 1990), but data from naturally fertile waters and soils are not so clear.

Fertility and productivity should not be confused: for example, rapid, efficient nutrient cycling greatly enhances the productivity of tropical rain forests even on soils of apparently low fertility. Nevertheless, some workers suggest richness within the tropics is highest on the more fertile soils (Gentry 1988; Wright 1992). Species-rich plant communities have been reported from soils with low nutrient concentrations (e.g. Huston 1980; Tilman 1982; but see Janos 1983).

3.2.2.1.3 Stress. Stressful habitats are those that are extreme in their environmental conditions, although what is 'extreme' may be relative to surrounding habitats (Brown 1981). Factors often considered stressful are high temperature, salinity, heavy metal concentrations, extremes of pH, and low oxygen and nutrient concentrations. In some 'stressful environments', diversities of organisms can be lower, for example in marshes and swamps, intertidal zones, hot springs, salt lakes, high arctic and alpine habitats (Williams 1981a; Brown and Gibson 1983). In others they can be higher (e.g. Keddy 1990). A very good example is the *fynbos* of South Africa, which has low nutrient status, but very high diversity (Cowling 1992). Some of the most hostile environments for macro-organisms, such as dried salt lakes, sulphur hot springs, inside rock under ice, hot deserts and deep ocean hydrothermal vents, are the habitats of unique microorganisms (Edwards 1990; Tunnicliffe 1991; Trüper 1992). At the same time, high plant diversity has been reported on serpentine or ultrabasic soils, which contain substances toxic to most plants (Whittaker 1954, 1975; Proctor *et al.* 1988; Jaffr 1992).

3.2.2.1.4 Heterogeneity. Structural complexity and food-resource heterogeneity within habitats commonly enhances

species diversity (Bell *et al.* 1991; Kolasa and Pickett 1991; Maeem and Colwell 1991). Examples include positive correlations between bird species diversity and foliage height diversity or vegetation structural complexity (MacArthur and MacArthur 1961; MacArthur *et al.* 1972), lizard species diversity and foliage volume diversity (Pianka 1967), fish diversity and sunken structures, and estimated average food chain length and vertical structure of the environment (Briand and Cohen 1987, but see Moore *et al.* 1989).

Within larger areas, diversity generally increases when a greater variety of habitat types is present (e.g. Johnson and Simberloff 1974; Cowling 1983). Analyses of large-scale patterns have found higher diversities of mammals, birds and flowering plants in areas with greater heterogeneity in elevation (Simpson 1964; Cook 1969; Johnson *et al.* 1968, Richerson and Lum 1980), although reptiles and amphibians may show some exceptions to this rule (Kiestler 1971; Currie 1991). Habitat heterogeneity created by low to moderate levels of natural disturbance (wave action, treefall gaps, landslides, fires) may also enhance biodiversity on a spatial scale larger than the disturbances themselves (Denslow 1980). Within the Amazonian rain forest intense fluvial action tends to lead to a greater degree of habitat heterogeneity than in other tropical areas, and helps to maintain the high species richness of that area (Tuomisto 1994). Recovery from disturbance creates successional habitats absent from undisturbed or universally disturbed regions.

Environments that vary through time are also heterogeneous, but unpredictable temporal heterogeneity (on scales from years to centuries) does not seem to enhance diversity (MacArthur 1975).

3.2.2.1.5 Biological interactions. Interactions and feedbacks among the species and non-living components of ecosystems also affect biodiversity. For example, accumulation of organic matter in soils results from complex interactions among climate, vegetation, parent rock material and soil organisms (Jenny 1980). In turn, soil organic matter affects soil structure and fertility and the diversity of plants (Janos 1983) and soil-dwelling organisms (Stanton 1979; Hendrix *et al.* 1986; Ewel *et al.* 1991). Because of the complexity of such feedbacks, little is known about the possible effect on biodiversity of spatial variation in biological interactions (see also Section 6).

3.2.2.2 Speciation and extinction

The processes that result in global patterns of species diversity have both geographical and historical dimensions and involve both speciation and extinction of taxa (Ricklefs and Schluter 1993). An understanding of these processes provides an insight into the natural persistence of taxa within areas (see Sections 4.3 and 4.4).

3.2.2.2.1 Species production. Speciation requires the accumulation of genetic differences between populations,

which is thought in most cases to depend on barriers to dispersal (Otte and Endler 1989). For this reason, the rate of speciation in many groups of organisms depends on both the geographical distribution of suitable habitat within a region and the dispersal abilities of individuals, as well as on genetic and other factors that influence the rate of differentiation between isolated populations. The importance of geographical isolation on species production is illustrated by the build-up of species groups on island archipelagos where opportunities for isolation exist between islands. For example, the many species of Darwin finches (Geospizinae) on the Galápagos Archipelago differentiated from an inferred single ancestral species (Lack 1947). The same lineage is also present on Cocos, an isolated island off the Pacific Coast of Costa Rica, but only as a single species.

Isolating barriers for one taxon may be crossed easily by others. One of the smallest islands with geographically isolated and genetically differentiated populations of a bird species is Jamaica, on which the streamer-tailed hummingbird (*Trochilus polytmus*) has distinct eastern and western subspecies. On the same island, however, and on many much smaller land masses, other taxa readily form new species. Lava flows and mountain ridges and valleys are effective isolating barriers for snails, crickets and fruit flies, and also many plants on the Hawaiian islands (Carlquist 1974; Carson and Kaneshiro 1976). The hundreds of species of cichlid fish in Lake Victoria possibly arose through the alternate isolation and rejoining of subpopulations in embayments as the level of the lake rose and fell with climate variation during the past million or so years (Greenwood 1984; Meyer *et al.* 1990).

3.2.2.2.2 Extinction. Two types of extinction require consideration. The first is the more or less constant background rate of extinction that biologists presume to occur within most taxa and regions. To the extent that this rate differs between taxa or regions, it may influence patterns of diversity. This type of extinction is poorly understood except that it is presumed to increase with decreasing size of island or habitat fragment (MacArthur and Wilson 1967). The second involves high rates of extinction within particular taxa or areas due to catastrophic events such as glaciations, volcanism, rapid climate change and novel pathogens (see Section 4.4).

3.2.2.3 Ecological theories of species diversity

3.2.2.3.1 Processes that add and remove species. Species diversity is a product of the histories of species accumulation and disappearance. In general, species are added to biotas either by the production of new species within regions or by migration from outside (Figure 3.2-6). Under natural circumstances, they can be eliminated due to total extinction or be removed by one of three processes. The first is by changes in physical conditions that make the

Figure 3.2-6: A schematic representation of the influence of regional and local processes on regional and local diversity. Arrows pointing towards a box increase diversity; those leading away reduce diversity. Habitat selection (the inverse of beta diversity) adjusts the relationship between regional and local diversity (from Ricklefs and Schluter 1993, Fig. 30.1, p. 351).

environment unsuitable. These may be very dramatic and extend over large areas as in the case of catastrophic disturbances. The second is by random fluctuations or chance (stochastic) events that affect birth and death rates in populations. The third is through exclusion by key biological factors, including competitors, predators, pathogens, pollinators and dispersal agents. These processes exert their population influences through local interactions between individuals.

The time scale and processes of species accumulation depend very much upon the spatial scale involved (see Section 4.1.3.4). For large regions, numbers of species build up primarily by evolutionary processes over extremely long periods. The life spans of vascular plant species are in the order of one to 5 million years (Niklas *et al.* 1983). After the end of the Cretaceous, many millions of years were required for large mammals to become as diverse as the dinosaurs they replaced. Similarly, the reconstitution of marine reefs following mass extinctions has often taken up to 10 million years, involving different groups of organisms – corals instead of rudist bivalves, for example (Kauffman and Fagerstrom 1993).

Within local areas, the build-up of diversity involves evolutionary processes to a lesser degree, with a significant component of diversity resulting from the colonization of the area in ecological time by propagules from nearby intact habitat and/or soil seed banks, hastened by the processes of succession when disturbance is involved. For example, over 1000 species were re-established on the Krakatau island group, Indonesia, within a century of its total destruction by volcanic explosion in 1883 (Simkin and Fiske 1983). Tiny islands of mangrove vegetation in Florida Bay, USA, experimentally defaunated by fumigation, regained their natural diversity within a couple of years (Simberloff and Wilson 1969; but see Simberloff 1976; Rey 1981).

3.2.2.3.2 Equilibrium versus non-equilibrium explanations. Equilibrium theories suggest that under ‘natural’ circumstances, species addition and loss are

balanced and, furthermore, that displacement from the ‘equilibrium’ value results in changes in speciation or extinction rate that tend to restore the system to its equilibrium state. In the extreme, local equilibrium theories presume that habitats become saturated with species and reach limits determined by the outcomes of local interactions between species. If equilibrium theories are correct, human-induced removal of species should eventually be compensated for by the appearance of new species.

Non-equilibrium theories suggest that diversity is not at equilibrium, and that the number of species increases or decreases depending on how the environment influences species production, exchange and extinction at any particular time. Drastic reductions in diversity during mass extinctions followed by slower recovery, and the gradual global increase in the diversity of many taxa such as flowering plants (Knoll 1986) and bony fish (Sepkoski 1992) illustrate non-equilibrium processes. At the regional scale, diversity represents the balance between extinction and species proliferation, and differences between regions are likely to reflect differences in either or both of these. At the local scale, diversity represents the balance between local extinction and movement of individuals between areas or habitats.

Human activities tend to exacerbate some of these natural causes of species removal. Regionally, the rate of human-mediated removal by extinction is probably often in excess of the natural evolutionary capacity for response (cf. Arroyo *et al.* 1992), although there is much variation from one region to another. Locally, removal clearly often exceeds the natural rate of migration and re-establishment. Studies are badly needed to compare the rates of local species addition, as a result of natural succession and local removal of species due to human activity.

Under non-equilibrium theories, given the slow rate of species production, maintenance of contemporary biodiversity within large regions depends primarily on preventing extinction. Preventing wholesale local erosion requires respect for the processes that maintain diversity. However, because of the nature of the ecological processes affecting species diversity, there will often be a good chance that species lost locally can be recuperated. While total extinction of a species affects both regional and local diversity, the long-term effects on ecological diversity of local extinction are uncertain (see Sections 4.5.3 and 5.2.2).

3.2.2.3.3 Theories of local coexistence. The number of coexisting species has been thought of as being determined by processes of species interaction (Wiens 1983). This general idea was inspired initially by competitive exclusion or elimination by predators seen in laboratory microcosms and by theoretical explorations of simple model systems (MacArthur 1972; May 1975a; Kingsland 1985). Alternatively, fugitive species may coexist with superior competitors by continually colonizing areas of unoccupied

space, as demonstrated by a variety of 'neutral' or 'lottery' models (Caswell 1977; Shmida and Ellner 1984; Chesson 1986, 1991; Tilman 1994) based on the ideas of Grubb (1977) and Sale (1977). In contrast to models of competitive coexistence, several versions of these lottery models do not require niche segregation (Hubbell 1979) and thus seem capable of explaining the coexistence of hundreds of species of tropical forest trees on a single hectare (Gentry 1988; Valencia *et al.* 1994).

3.2.2.3.4 Terrestrial landscape, marine environment and freshwater diversity. Strategies for species preservation will depend on knowledge of the temporal and spatial scale of the processes that naturally maintain species within particular areas and habitats (Ricklefs *et al.* 1984). Unfortunately, these processes have not been well resolved by biologists and there has been a bias towards terrestrial ecosystems.

Local diversity may be enhanced by the exchange of individuals between habitats. In relation to terrestrial ecosystems, this has been called the 'mass effect' by Shmida and Wilson (1985), and such effects, although less studied, should also be relevant to marine and freshwater systems. Some species may not be able to persist in a particular habitat because offspring production is insufficient to replace deaths. However, the deficits of these so-called sink populations (Pulliam 1988) may be compensated by the movement of individuals from habitats in which the species is more productive (source populations). Thus, species persistence in natural habitats strongly depends on the dynamics of the regional population (metapopulation) and the persistence of suitable habitats (see Section 4.5).

Differences in species diversity between localities may depend in part upon habitat heterogeneity within the region. For example, Cowling (1983) showed that within both *fynbos* and forest biomes in South Africa, increasing species richness in 100 m² plots is correlated with increasing phytochorological diversity (habitat complexity). In freshwater habitats such as lakes, habitat conservation (cf. Cooke and Welsh 1993) is clearly essential for the maintenance of these kinds of processes. As Sherman (1994) points out, the sustainability of coastal ecosystems could be greatly enhanced by implementation of a more holistic and ecologically based strategy for assessing, monitoring and managing coastal ecosystems. During the past decade considerable effort has been made by coastal countries in conducting surveys of marine populations as part of their resource assessment. Although most of the studies have been directed to economically important species, recent efforts have been initiated that include multispecies communities at different trophic levels for several large marine ecosystems (AAAS 1990; Sherman 1994). Similar efforts are under way for freshwater ecosystems including lakes, reservoirs and river basins (Magnuson *et al.* 1995).

3.2.2.4 Tests of theories of local coexistence

Theories of local coexistence of species are difficult to test because communities develop over evolutionary periods and experimental approaches are therefore difficult to interpret. Two approaches have been taken. One is to examine the primary assumption of local coexistence theory, namely that populations influence one another through competition, predation, parasitism, mutualism, and so on (see Section 4.5). The second examines several predictions of local coexistence theory, including those of community saturation and convergence.

3.2.2.4.1 Community saturation. Saturation refers to an upper limit to local richness, imposed by local interactions, that is independent of the size of the regional colonization pool (Terborgh and Faaborg 1980; Cornell and Lawton 1992; Cornell 1993). If interspecific competition and other interactions acted as major organizing forces in ecological communities, then these interactions would limit the number of species that can coexist locally in a stable community. According to this model one could expect local communities to show an upper threshold, or saturation level of diversity, regardless of the regional species pool, so that alpha and gamma diversities are uncorrelated.

Testing for saturation involves comparing species richness data in small-scale samples of uniform area among comparable habitats in different regions. The regions must differ in the size of the regional species pool. If local richness increases with regional richness at sites with smaller regional pools but levels off at a 'ceiling' value in more diverse regions, the data are taken to support saturation. If local richness increases steadily with regional richness, with no sign of levelling off, the data do not support saturation. This null result is termed 'proportional sampling', that is, local richness increases proportionately with the size of the regional species pool when sample area is held constant.

Cornell (1993), reviewing the literature available, found contrasting results and only weak support for competitive saturation (Table 3.2-1). He pointed out that whether a particular model of local coexistence predicts saturation depends on its assumptions. Models predicting saturation are based on the assumption that coexisting species evade competition by occupying diversified ecological niches. Models of local coexistence that do not require niche differentiation do not predict saturation. Thus, both the data and the current body of theory are ambivalent regarding saturation.

3.2.2.4.2 Regional enrichment. The alternative to saturation is referred to as 'proportional sampling' or 'regional enrichment'. In this model, species are independently distributed according to habitat tolerances and historical constraints. Within their region of occurrence, species will assort more or less independently from each other into local assemblages. Therefore, the local assemblage is drawn from

Table 3.2-1: *The results of comparisons of local to regional diversity are mixed, but generally support regional enrichment rather than saturation (from Cornell 1993). Examples are of tests of the competitive saturation/proportional sampling predictions.*

Birds on West Indian Islands: Terborgh and Faaborg (1980), saturation; Ricklefs (1987) and Wiens (1989), no saturation.
Cynipine gall wasps on oaks in California: Cornell (1985a, b), no saturation.
Wood-boring scolytid beetles: Stevens (1986), no saturation.
Herbivores on bracken: Lawton (1990a, b), Lawton, Lewinsohn and Compton (1993), no saturation.
Fig wasps in South Africa: Hawkins and Compton (1992), no saturation.
Inflorescence-utilizing insects on Asteraceae: Zwölfer (1987), Lewinsohn (1991), no saturation.
Parasites on amphibians: Aho (1990), suggests saturation.
Parasites on fishes: Aho and Bush (1993), suggests saturation.
Freshwater ciliates: Taylor (1979), no saturation.
Leaf miners on oaks: Opler (1974), no saturation.
Coral reef fishes: Westoby (1985), no saturation.
Ants in sclerophyllous vegetation: Westoby (1985), suggests saturation.
Invertebrates in seagrasses: Heck (1979), suggests saturation.
Crustaceans on corals: Abele (1984), suggests saturation.
Fishes on corals: Bohnsack and Talbot (1980), suggests saturation.

Data sets through Aho and Bush (1993) are large; the rest are small.

the regional pool and is little affected by internal community dynamics (Cornell 1985a). When ecological saturation does not apply, comparisons among communities in similar habitats in different regions should reveal a proportional relationship between local and regional taxic richness. Saturation is indicated by a plateau of local diversity with increasing regional taxic richness (Figure 3.2-7).

The results of the above kinds of comparisons (Table 3.2-1) are mixed, but generally support regional enrichment rather than saturation (Cornell 1993). Support for the regional enrichment model suggests that regional processes are important to the maintenance of local species diversity. Unfortunately, how these processes work and how they interact to influence the outcomes of local species interactions are very poorly understood (Hawkins 1993). It is worth noting that except for Aho and Bush's (1993) work on parasites, studies on saturation are from 1985 or earlier, while those on regional enrichment are later. This indicates a shift in the attitude of ecologists away from local effects and towards regional process hypotheses. Whether this represents new insight or fashion remains to be seen.

3.2.2.4.3 Community convergence in species diversity. If species diversity is regulated by local interactions among individuals, then communities occupying similar environments in geographically isolated regions (e.g. different continents) should converge around a similar number of species. Tests of convergence are powerful for evaluating the assertion that species richness is determined by local processes.

The biogeographical literature offers as many cases of nearly equal species diversities as of highly dissimilar diversities in similar habitats in different parts of the world (Schluter and Ricklefs 1993). For example, lizard species richness is similar in Mediterranean scrub in California (9 species) and Chile (8 species, Fuentes 1976) but dissimilar in deserts in Australia (27) and North America (7, Pianka 1986). Ant species richness is identical in deserts of Arizona (25) and Argentina (25, Orians and Solbrig 1977), but bee diversity varies in Mediterranean scrub between California (177) and Chile (116, Mooney 1977). Although total plant species and generic richness is lower in central Chile than in California, richness is modally similar when other temperate areas are considered (Arroyo *et al.* 1995a).

Schluter and Ricklefs (1993) divided local species diversity into two components, one attributable to the local habitat and the other to the region in which local habitats are embedded. They defined convergence as the habitat-related component, and estimated the relative magnitudes of the two components as the fraction of the overall variance in diversity that each accounted for in an analysis of variance. They found cases in which convergence predominated, other cases governed by the regional effect, and some in which the two effects were equal. In most of the data sets analysed, local species richness varied between regions within closely similar habitat types by a factor of 1.4 to 1.7, indicating a pattern of strong convergence together with a consistently important regional effect on local diversity.

3.2.2.5 The relationship between local and regional diversity

Until recently, local and regional diversity were treated as separate issues and were addressed by different specialists. The number of co-occurring species was a problem to be tackled by community ecologists concerned with models of interspecific interactions. They treated the local community as a self-contained arena in which population interactions determine how many, and which, combinations of species can coexist (Drake 1990, 1991). Regional diversity, on the other hand, was a question for biogeographers who concerned themselves with rates of speciation, continental drift and other large-scale questions, without specifying how these would relate to population and community processes.

From the standpoint of the conservation of biodiversity, understanding the relationship between local and regional diversity is essential. The link between local and regional species richness indicates the degree to which regional processes leave their imprint on the local community. This link also emphasizes the intimate connection between the maintenance of local diversity and the preservation of the landscape and regional settings (Noss 1983; Franklin 1993). The tighter the link between levels, the more dependent is the local community on surrounding habitats and the total landscape.

Recent theory has begun to explore the linkage between diversity patterns and processes at different spatial levels, recognizing that there are reciprocal influences (Brown and Maurer 1989). Community dynamics are seen as being affected by regional and historical processes: regional diversity, in turn, integrates population and community processes at the local level.

3.2.2.5.1 Empirical evaluation of the relationship between local and regional diversity. Beta diversity can be used to ascertain to what degree local and regional diversity are functionally linked, although the actual analytical procedures are still nascent and open to discussion.

Empirical studies of this relationship are still scarce. There are two difficulties. First, existing data are mostly inadequate because both local and regional diversity estimates are required and, for historical reasons, few cases offer this possibility (see Table 3.2-1). Second, if estimates of regional diversity are derived from summing species across actual local samples, as will be the case for most empirical studies, gamma and alpha diversity will tend to be correlated when few local estimates are available. Estimates of gamma diversity will become progressively independent of individual alpha estimates as the number of studied sites increases.

To examine the local-regional relationship several distinct kinds of communities or habitats with strong contrasts in overall diversity must be considered. Such comparisons may be found among communities occupying

Figure 3.2-7: Theoretical relationship between local and regional richness in communities exhibiting proportional sampling and those exhibiting richness ceilings (saturation). The relationship labelled 'boundary' represents local richness equal to the regional pool and is an upper boundary on local richness (from Ricklefs and Schluter 1993, Fig. 16.5, p. 181, Fig. 22.1, p. 245).

habitat areas of different sizes. Assemblages of phytophagous insects on various host plants differing in geographical ranges provide examples of such analyses, and offer mixed support for local and regional process models (Table 3.2-1). One must also remember that these studies compare the faunas of different host plants within the same region, treating each host plant as a different region. Thus, the results of such comparisons may depend on the particular interactions of herbivores with their host plants.

Cynipine wasps on oaks. Cornell (1985a, b) examined the numbers of species of gall-making cynipid wasps on various oak species with different geographical ranges in the western USA. He found the expected relationship of regional diversity to geographical range of the oaks: species with larger ranges harboured more species of gall-forming wasps. Moreover, local diversity was also related to both geographical range and total (gamma) diversity, with no evidence for an upper limit to local community size. Thus, this system conforms to a regional enrichment model.

Additional support for such a model is provided by the comparison of assemblages of insects feeding on bracken in different parts of the world, which show a clear relationship of alpha to gamma diversity, again with no evidence for saturation (Lawton *et al.* 1993). Likewise, in a study of beetles in rotting tree branches, Stevens (1986) obtained results essentially similar to those of Cornell and Lawton (1992).

Insects on flowerheads. Different results were obtained in two studies of flowerhead-feeding insects associated with Compositae. Both in Europe (Zwölfer 1987) and in Brazil (Lewinsohn 1991), alpha and gamma diversity are seen to be correlated, but this is partly due to the sampling problem referred to earlier. Contrary to Cornell's and

Lawton's results, gamma diversity, but not alpha diversity, correlates with host plant area, once sampling effort is factored out (through path analysis, Lewinsohn 1991). These results show that, for these assemblages, beta diversity is largely responsible for the greater species richness of insects feeding on more widespread plants. However, local and regional diversity are still correlated although more weakly than in the foregoing cases, which indicates that they are to some extent linked.

West Indian land birds. Censuses of nine matched habitats, ranging from arid scrub to cloud forest, on five islands of different area and distance from continental coastlines (Cox and Ricklefs 1977; Wunderle 1985), showed that increasing regional diversity (total number of species per island) is accompanied by continuous increases in both alpha and beta diversity. Indeed, both components increase in direct proportion to the square root of gamma diversity. There is some evidence that a similar relationship holds for the diversity components of mangrove forests (Ricklefs and Latham 1993).

The flora of the Mediterranean-type climate region of central Chile. Although total plant species and generic richness (gamma diversity) is lower in central Chile than in California (Arroyo *et al.* 1995a), regional woody species richness, alpha diversity and the woody component of alpha diversity are higher in central Chile (Mooney 1977). Higher alpha diversity in Chile has been attributed to a greater degree of disturbance (Mooney 1977). However, regional enrichment, expressed through the richer woody flora, offers an alternative partial explanation at least for higher alpha diversity (Arroyo *et al.* 1995a).

Although these results are a useful starting point for discerning the major patterns, they do not distinguish unequivocally between local- and regional-process models. The lack of evidence for upper thresholds need not imply that local dynamics are inconsequential to both local and regional diversity. Both alpha and beta diversity tend to increase with gamma diversity, indicating a balance between regional and local processes. The important point is that patterns of diversity represent a continuum of scale. Additional work to address these questions with a wider variety of organisms and habitats is badly needed.

3.2.2.6 Taxon-specific patterns of diversity: dispersal

The limited dispersal and colonization abilities of some taxa and lineages contribute to natural differences in biodiversity at local and regional scales. Limited dispersal capacity will also hinder recuperation of biodiversity in naturally disturbed or managed ecosystems where the extraction of a resource has exaggerated initial effects on the remaining biota. Knowledge of dispersal capacity is therefore fundamental to any understanding of diversity patterns *per se* and for predicting how biodiversity will respond to management.

Biodiversity often decreases with distance from source populations, and is most constrained by dispersal in areas that are surrounded by dissimilar habitat, such as oceanic continents and archipelagos, temperate ecosystems isolated on tropical mountain tops, moist ecosystems in arid regions, and isolated lakes (Carlquist 1965; Collevaux 1993). For example, there are fewer species of algae in lakes on the remote Galapagos Islands and remote Easter Island than lakes of the same size on the continent (Collevaux and Steinitz-Kannan 1980; Collevaux 1993). Except for bats, terrestrial mammals have limited dispersal abilities, and their diversity decreases with increasing isolation on Canadian, British and Danish islands (Grant 1970; Table 3.2-2). Poor dispersal can also result in decreasing diversity of birds, rodents and lizards with distance along peninsulas (Taylor and Regal 1978), and may contribute to loss of diversity from fragmented habitats (Harris 1984; Lovejoy *et al.* 1986). However, regional diversity in lineages with good dispersal is sometimes lower than in lineages with poorer dispersal because lack of reproductive isolation among populations can reduce speciation (Ricklefs and Cox 1972). Different taxonomic groups, moreover, exhibit different degrees of reduced diversity (disharmony) with isolation because of their particular dispersal means, sensitivity to environmental stress, reproductive biology, minimum population sizes, and the particular behaviour patterns of animal dispersers and pollination vectors themselves (Carlquist 1965; Bush and Whittaker 1991; Whittaker and Jones 1994). For example, the diversity of amphibian families in the Philippine archipelago decreases with distance from mainland Borneo more steeply than the diversity of lizard families (Darlington 1957; Carlquist 1965). Bermuda has the northernmost coral reefs because the Gulf Stream deposits coral larvae from the tropics, but reef fish cannot survive the long journey (Ray and Ciampi 1956). Williamson (1981) compared oceanic islands of equal area where the climates of the mainland and islands were similar and suggested that differences in dispersal resulted in the nearshore Channel Islands (UK) having more than twice as many vascular plant species, four times as many breeding bird species, but the same number of fern species as the more distant Azores. Some lineages of birds are apparently absent from Caribbean islands because of limited dispersal abilities (Ricklefs 1987).

3.2.2.6.1 Passive dispersal. Many organisms use wind or water currents to effect their dispersal. Rakata was first colonized by wind-blown and water-borne seeds following the volcanic explosion of Krakatau (Bush and Whittaker 1991). Gametes of many marine invertebrates and fish are released into currents which disseminate their pelagic larvae (Scheltema and Williams 1983; Vermeij *et al.* 1985; Underwood and Fairweather 1989; Leal and Bouchet 1991). Passive dispersal may be more efficient than

expected because dispersers are concentrated by prevailing winds or currents, as in coral larvae deposited in Bermuda by the Gulf Stream (Ray and Ciampi 1956), or their distribution may be otherwise non-random. For example, in a study in Panama, Augspurger and Franson (1988) found that more wind-dispersed tree seeds fell into forest light gaps than expected. Furthermore, spores, mites, small insects and seeds are thought to be deposited disproportionately in orographic rain on high islands and mountain tops because such minute biota act as nuclei for raindrops (Gressitt 1961; Carlquist 1965; Ehrendorfer 1979).

3.2.2.6.2 *Active dispersal.* Many animals disperse under their own power, but they differ in their ability or inclination to do so. Although most birds can fly, their diversity is reduced with distance from the mainland in the Lesser Antilles (Table 3.2-3; Ricklefs 1977b) and on islands off California (Power 1972; Williamson 1981). Some animals that evolved in ecosystems with large areas of contiguous habitat will not cross rivers or forest gaps (Willis 1969, 1979; Diamond 1971; Terborgh 1975; Karr 1982; Cracraft 1985a; Newmark 1991), and are more likely to become locally or regionally extinct through forest fragmentation (Newmark 1991; Lovejoy *et al.* 1986; see also Section 4.5). In contrast, species that utilize widely dispersed or patchy resources may regularly cross large areas of unsuitable habitat (Lack 1976; Karr 1982; Lovejoy *et al.* 1986).

3.2.2.6.3 *Vectors.* Many plants (Carlquist 1965; Bush and Whittaker 1991), fungi (McIlveen and Cole 1976) and invertebrates (Kuschel 1962) depend on animal vectors for dispersal and, where applicable, pollination. Capacity to colonize new areas successfully and to recolonize previously occupied areas is highly dependent on the behavioural characteristics and geographical distribution of such vectors. For example, truffle fungi are obligate mycorrhizal symbionts of trees and are normally dispersed within forest boundaries by small mammals that consume

Table 3.2-2: Rank correlations for the number of species of mammals on islands (from Grant 1970).

Variable	Canadian Is.	British Is.	Danish Is.
Area	+ 0.16	+ 0.04	+ 0.67*
Isolation	+ 0.43**	+ 0.68***	+ 0.63*

* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

them (Maser *et al.* 1978; Malajczuk *et al.* 1987; Blaschke and Baumler 1989). Although rodent dispersal is efficient, it limits movement of truffles between (and diversity in) forests on isolated mountain ranges in the Great Basin of North America (Fogel 1992). The reluctance of pollinators and avian seed dispersers of certain plants to move across gaps raises concern for the effects of logging and fragmentation on plant diversity in tropical forests and particularly southern temperate forests where, in contrast to the northern temperate forests, animal dispersal and pollination is commonplace (Lovejoy *et al.* 1986; Armesto *et al.* 1987; Newmark 1991; Riveros *et al.* 1991; Thiollay 1992). Some birds and bats are known to fly long distances bearing propagules of plants (Carlquist 1965; Bush and Whittaker 1991; Whittaker and Jones 1994) and fungi (McIlveen and Cole 1976). Dispersal of fruits by bats and birds is often delayed, however, until other trees serve to attract them (Bush and Whittaker 1991; Parrotta 1993).

3.2.2.6.4 *Interaction of dispersal with breeding system.* The probability of successfully colonizing an isolated island or widely separated habitat patch on a continent is greater for self-fertile and asexually reproducing species of invertebrates and fungi (Baker 1955; Carlquist 1974; Ehrendorfer 1979; Barrett 1985) than for outcrossing species. Likewise, the probability of colonization in a

Table 3.2-3: Multiple regression—partial correlation analysis of factors influencing species diversity on West Indian Islands (from Ricklefs 1977).

Islands	Size	Sample area	Altitude	Distance to mainland	Distance to nearest island	Multiple R^2

species adapted to generalist pollinators will be higher than when highly specific pollinators are required. These same principles apply to recolonization following large disturbances, such as glaciation, in continental areas, and to smaller disturbances such as those occurring following the harvesting of a key resource. This may explain the prevalence of self-fertility among colonizing and ancestral island plant species (Carlquist 1965, 1974; Barrett 1985; McMullen 1987; Taylor 1993). Obligate outcrossing may increase the likelihood of maintaining viable populations through time (Carlquist 1965, 1974; Sakai *et al.* 1989; Webb and Kelly 1993) but the over-abundance of obligately outcrossing dioecious species in island floras may have other causes (Carlquist 1965; Baker 1967; Ehrendorfer 1979; Baker and Cox 1984; Webb and Kelly 1993).

Many plants on distant islands are pollinated by a few generalists due to poor dispersal of pollinators (Carlquist 1965, 1974; Ehrendorfer 1979; McMullen 1987; Webb and Kelly 1993). Large or dense source populations provide more dispersers (Williamson 1981), which may be critical for the establishment of sexual animals such as birds and mammals. In other phyla, however, self-fertility and asexuality in source populations can favour their establishment on islands, and these traits are more common in sparse populations that are often at the limit of their range (Barrett 1985). It is not known if this amplifies founder effects (see Section 4.2) and results in increased diversity among populations on different islands.

For continental floras, the breeding system information now available suggests that obligate outcrossing via self-incompatibility and dioecism increases strongly with longevity (Bullock 1985; Arroyo and Squeo 1990; Arroyo and Uslar 1993). Within any given life-form it has been demonstrated recently that dependence on external pollination vectors can be as high, if not higher, in temperate plant communities than in the tropics (Arroyo and Squeo 1990; Arroyo and Uslar 1993). Because few rigorous community surveys of pollination have been carried out to date, it is not clear whether or not tropical species always show a greater degree of pollinator specificity than their tropical counterparts. In a world of rapidly changing landscapes, subject to the effect of global climatic change, more detailed knowledge of the reproductive biology of species is required in order to determine the overall capacity of species to respond, and thereby to be able to make informed predictions about future change (Arroyo *et al.* 1993).

3.2.2.7 History, biogeography and diversity

3.2.2.7.1 Non-convergence and the roles of history and biogeography. Patterns of biodiversity follow general patterns in physical conditions of the environment, such as insolation, temperature, precipitation and salinity. Striking deviations from ecologically 'predictable' levels of

diversity suggest, however, that the histories and biogeographical positions of different areas have also left their imprint on both regional and local diversity (Brooks and McLennan 1991). The examples presented in some detail above concerning variation in the diversity of mangroves and temperate forests indicate that the numbers of species in diverse and depauperate assemblages in matched habitats or biomes may vary by factors of five or ten, and average about 1.5 (Schluter and Ricklefs 1993). Such diversity anomalies have presumably resulted from differences in region-scale processes of species production, exchange and extinction.

3.2.2.7.2 Diversity anomalies and geographic and historical circumstances. Two case studies illustrate how special historical and geographical circumstances can influence diversity patterns. As we have seen, the temperate broad-leaved forests of eastern Asia contain about three times as many tree species as those of eastern North America and six times as many as those of Europe. Furthermore, the Asian forests contain a marked proportion of taxa derived from tropical, rather than strictly temperate, groups. Finally, the fossil record shows that during the middle Tertiary, the European tree flora equalled that of Asia in diversity, both of these being far more diverse than the flora of eastern North America (Latham and Ricklefs 1993b; Table 3.2-4). The simplest interpretation of these data is that the high Tertiary diversity of Eurasia resulted from a direct connection through continuous forest habitat between temperate east Asia and tropical Southeast Asia, and that North America was relatively isolated from both Eurasia and tropical South America. More recently, cooling trends and eventually glaciations had their greatest impact on the flora of Europe, with the east-west barriers of both the Alps and the Mediterranean basin blocking the southward displacement of warm-temperate species to southern refuges.

The greater tree species diversity of mangroves in the Indo-West Pacific region compared to the Atlantic-Caribbean region appears to be related to two processes that have occurred more readily in Southeast Asia than elsewhere, namely the invasion of mangrove habitat (i.e. salt water) by elements of the terrestrial flora, and the proliferation of taxa by speciation within the mangrove flora (Ricklefs and Latham 1993). The first presumably requires evolutionary modification for tolerance of salt and anoxic sediments, and probably occurs most readily in regions of high precipitation in which the transition between freshwater and salt water is gradual and continuous. The second undoubtedly requires the geographical isolation of subpopulations afforded by complex geography and ocean currents. The particular way in which these factors have influenced mangrove diversity in different areas has not yet been determined, but the numerous islands and complex currents in the

Malesian region might produce ideal conditions for reproductive isolation.

3.2.2.7.3 *Congruence and independence of histories.* Congruence of geographical patterns of distribution may occur among taxa when they utilize similar paths of dispersal or when several taxa are subdivided by the same tectonically and climatically produced barriers to dispersal (Nelson and Platnick 1981). The latter produces what are known as vicariant patterns of dispersal. Such barriers can be as geographically extensive as sea-floor spreading separating formerly united continents, or as local as a change in drainage pattern (Cracraft 1973). Typically, vicariant patterns are identified by the high degree of congruence among the relationships of the taxa in each area, but vicariant processes do not lead to the increase of diversity within each fragment, unless the pieces of area re-coalesce. High diversity is more likely to accumulate through moderate levels of dispersal between suitable islands of environment, but the tectonic histories of some parts of the Earth, particularly the Caribbean, and the region from the Mediterranean through Southeast Asia to New Zealand, have been so complex that vicariant processes may have been responsible for considerable build-up of diversity .

3.2.2.7.4 *Differential extinction.* It is well known that extinction has moulded biodiversity patterns in temperate biota, but its more general influence is poorly understood. Minimum ages of taxa may be estimated from fossil data where these are sufficiently detailed. An example for families of mammals is given in Figure 3.2-8, in which it can be seen that the West African taxa are generally younger, indicating more active evolution and speciation in the African fauna, but that the oldest taxa are also from Africa (Ricklefs and Schluter 1993). A comparison of local forest bird faunas from temperate North America (Illinois) and tropical Central America (Panama) showed that the tropical fauna had twice as many species as the temperate fauna, and that the taxa comprising the tropical fauna were, on average roughly twice the age of the temperate taxa (Ricklefs and Schluter 1993). Thus, the difference in diversity may have resulted from the difference in the ages of lineages in each area (Farrell and Mitter 1993).

The relative roles of speciation and extinction in producing global patterns of species diversity, particularly the general increase in species number from high latitudes towards the Equator, is a matter of considerable debate. If species accumulate in the tropics due to low extinction rates, one would expect to find the average age of tropical taxa to be higher than that of the temperate taxa. If, on the other hand, tropical diversity were driven by high speciation rates, taxa should be relatively younger there.

Another approach to estimating the relative ages of biotas has been to calculate the ratio of species to genera, with the assumption that the higher ratios indicate

Table 3.2-4: Contemporary and fossil diversity of trees from three temperate areas. The fossil record shows that during the middle Tertiary, the European tree flora equalled that of Asia in diversity, both of these being far more diverse than the flora of eastern North America (from Latham and Ricklefs, 1993b, Table 26.8, p. 304).

	Europe	Asia	North America	
			Western	Eastern

Total fossil genera	130	122	75	60

relatively high rates of speciation and more recent derivation of a biota on the species level. Sampling and different taxonomic concepts become problematic in such comparative studies. One example shows that species to genus ratios in tropical trees from a small area in Costa Rica are slightly less than those in the temperate tree flora of North America (Ricklefs 1989). Rickleffs and Renner (1994) developed a non-linear mathematical relationship between number of families and genera for flowering plants. In fact, in general, diversity at different taxic levels often varies in parallel, indicating that global patterns of species diversity are, on the whole, very old (Arroyo *et al.* 1995a; Williams and Gaston 1994; Williams *et al.* 1994). As always, however, such generalizations are tempered by exceptions. In the Cape Flora of South African the number of species per genus is unusually high (> 8 per genus, on average) even for Mediterranean-type climate floras (cf. Raven and Axelrod 1978), indicating recent, rapid speciation (Goldblatt 1978).

3.2.2.7.5 *History and ecological diversity patterns.* As a stronger theoretical framework emerges, it is becoming evident that patterns of biodiversity in natural settings showing strong ecological correlations may reflect history rather than the product of ecological equilibria of species diversity determined by the outcome of species interactions. The decrease in diversity with increasing distance from the Equator may in part reflect the relative age, geographical extent, and different historical patterns of barrier formation and consequent biotic disruptions of tropical, temperate and boreal environments. During most of the early Tertiary period, global climates were less stratified than they are at present and extended to high latitudes in both the northern and southern hemispheres (Axelrod *et al.* 1991). Possibly, the greater area and antiquity of modern tropical environments has been a major factor in their present-day diversity. In particular, the extension of tropical groups to temperate climates required the evolution of frost resistance. This may have been so strong a climate barrier, as it is at present (and just as salt

Figure 3.2-8: Distribution of ages of taxa in temperate (northern Eurasia: hatched bars) and tropical (central-western Africa: solid bars) mammalian faunas (from Ricklefs and Schluter 1993, Fig. 30.6, p. 362, after Stehli *et al.* 1969).

tolerance is for mangrove plants), as to restrict the invasion of temperate environments from the tropics. Given enough time, diversity at high latitudes might increase to levels now seen in the tropics (e.g. Wilson and Taylor 1967), but the present disparity would then have arisen from historical, non-equilibrium causes (Farrell *et al.* 1992; Farrell and Mitter 1993; Latham and Ricklefs 1993b).

3.2.3 Concluding comments

Distributional studies of biodiversity patterns show that each region has had a unique phylogenetic, geographic and ecological history that has shaped contemporary biodiversity. While there are broad geographical patterns, the complexity of regional and local situations diminishes the predictive value of these patterns and emphasizes that much more attention must be given to understanding local processes and past history. A more geographically balanced and integrative effort among taxonomists and ecologists, at both the research and conservation levels, is essential in order to safeguard all ecological systems and their component species. This perspective emphasizes the intrinsic value of each area irrespective of its richness, and the need for careful assessment of the relationship of any given biota to others nearby, before arriving at conservation and management plans.

Human activity tends to modify the balance of present-day ecological factors resulting in shifts in the equilibrium between contemporary ecological and evolutionary forces as they affect the production and extinction of biodiversity. More than anything else, there is an urgent need for humans to moderate their activities to bring them into line

with natural ecological processes. The sustainable management of biodiversity will depend upon our ability to predict the capacity of ecosystems to respond to alterations in specific biodiversity components, and to incorporate these findings into adaptive management plans before it is too late. This requires prior knowledge of total biodiversity, of the strength of species links, and above all of the ecological processes that maintain biodiversity.

This assessment shows that much past work on patterns of diversity has been documentary, and concentrated at the global and regional scales. In order to solve many of the problems that lie ahead, careful assessment of local diversity and its relationship to the landscape scale is called for. With regard to the sustainable use of biodiversity components, one way of moving ahead quickly will be to assess the response of biodiversity across different groups of organisms in well-planned, experimental interventions of various intensities, and at spatial scales that are commensurate with the alterations caused by humans.

3.3 Endemism and biodiversity

3.3.1 Endemism: concepts and perspectives

This chapter outlines the conceptual and empirical issues relating to endemism and how patterns of endemism are influenced by spatial scale, taxon age and relationships, population abundance and different human perceptions and biases.

3.3.1.1 Background

Endemic taxa are those restricted to a specified geographical area. Thus, the concept of endemism, as presently conceived, is a relative one, and the endemic status can have varying biological significance depending on the size and location of the geographical area under consideration. Endemism as a concept has a long history in biology, dating back to De Candolle (1820). As a research topic, however, endemism has attracted little attention in the field of modern biogeography. Much early research on endemism pertained to vascular plants in temperate areas, for which several reviews have appeared over the past two decades (Prentice 1976; Kruckeberg and Rabinowitz 1985; Gentry 1986; Major 1988). In the tropics, where surveys of endemism began somewhat later, vascular plants, birds and butterflies have been studied. Reviews on endemism for animal groups have focused on island endemics (e.g. Briggs 1966; McDowall 1968; Johnson and Stattersfield 1990; Groombridge 1993), Australasian vertebrates (Cracraft 1991) and global bird faunas (ICBP 1992). Few studies to date have considered fossil information. For example, the perception of endemism in New Caledonian birds changed after it was discovered that rats introduced by humans induced extinction in the fragile sclerophyllous ecosystems of the west coast of the island (Balouet and Olson 1989; Chazeau 1993).

3.3.1.2 Categories of endemics

Endemics may be categorized according to their spatial distribution, inferred evolutionary age and affinities, and abundance. In terms of spatial distribution, endemics may occupy limited geographical ranges – i.e. have a limited ‘extent of occurrence’ – and also have a limited ‘area of occupation’ within their geographical range (Gaston 1991). At the other extreme, they may have relatively large absolute geographical ranges when the circumscribed geographical area is extensive (e.g. the continent of Australia), and often be abundant within those large ranges. To a degree, recognition of endemic status relies on the relative size of the geographical range of the species, genus or other higher taxon under consideration, in relation to the total range of the genus, family, etc. to which that taxon belongs (cf. Bykov 1983; Williams *et al.* 1993).

In practice, endemics are loosely and commonly categorized in four contexts:

1. Site or restricted area (e.g. arthropod groups on individual summits in the crystalline mountains of Tanzania; Lovett and Wasser 1993).
 2. Biotope (e.g. as with *Quercus durata* confined to serpentine outcrops).
 3. Biogeographical region (e.g. as for turkeys, Meleagridinae, confined to the Nearctic Biogeographical Region).
 4. Political area (e.g. as with the maned sloth *Bradypus torquatus*, endemic to Brazil).
- Engler (1882) provided one of the first classifications of endemics according to their evolutionary age. He recognized:
1. Neoendemics, comprising clusters of closely related species and subspecies that have evolved relatively recently (e.g. the hundreds of species of cichlid fishes in Lake Malawi; Ribbink *et al.* 1983).
 2. Palaeoendemics, comprising phylogenetically high-ranking taxa, usually monotypic sections, subgenera or genera that may be regarded as evolutionary relicts (e.g. *Welwitschia mirabilis* of the Namib Desert).
- This classification has been greatly extended and widely used by botanists (e.g. Willis 1922; Cain 1944; Favarger and Constandriopoulos 1961; Stebbins and Major 1965; Hopper 1979), but rarely by zoologists (e.g. Machado 1992).
- Cytological data, as indicated by a more comprehensive treatment of European mountain flora endemics (Favarger and Constandriopoulos 1961), can provide a more rigorous basis for assessing the relative age and affinities of plant endemics. In this study, four categories were recognized according to taxonomic rank and ploidy level:
1. Palaeoendemics — ancient isolated taxa with a high ploidy level, whose diploid ancestors are extinct or unknown.
 2. Schizoendemics – vicariant species of equal ploidy level, resulting from either gradual or rapid divergence.
 3. Patroendemics – restricted, diploid species that have spawned younger, widespread polyploid species.
 4. Apoendemics – polyploid endemics that are derived from widespread species of a lower ploidy level.
- Schizo-, patro- and apoendemics are further subdivisions of neoendemics.
- Some problems associated with this classification are that (1) age is regarded as a categorical, rather than a continuous, variable (cf. Cronk 1987); (2) the establishment of relationships between taxa lacks rigour

(cf. Nelson and Platnick 1981); and (3) many paleoendemism are diploid (indeed, ancient relictual status is the most consistent attribute of this category; Stebbins and Major 1965).

Phylogenetic methods, which consider the distribution of characters among taxa in a cladistic context (Nelson and Platnick 1981; see Section 2.1), can be used to characterize endemics in terms of hypotheses of relative age and propinquity of descent. In this context, low-ranking taxa correspond to neoendemism and high-ranking taxa to palaeoendemism (e.g. Linder and Vlok 1991; Stiasny and di Pinna 1994). An absolute estimate of the age of endemics can be given when congruent phylogenetic relationships correlate with identifiable historical events (e.g. Rosen 1979; Cracraft 1986).

In contrast with treatment of the concept of rarity (3.2.1.5), the categorization of endemics according to their population abundance has received little attention. Geographic range as a categorical variable (wide/narrow) has been used as one of the factors in defining seven forms of rarity recognized for plants (Rabinowitz *et al.* 1986). Endemics (narrow range) may belong to any of four categories of rarity according to biotope specificity (broad or eurytopic/restricted or stenotopic) and local population size (somewhere large/everywhere small) (see also Gaston 1991, 1994). Most treatments of endemism emphasize biotope specificity, but few consider population size (but see Given and Norton 1992). There is an urgent need to categorize endemics more carefully in relation to their population abundance, since population size has important conservation implications (Mace *et al.* 1992; Mace 1993; IUCN 1995), and will be especially relevant when an endemic species is also a rare species. In South Africa, some highly localized endemic damselflies are by far the dominant species in their specialized habitats (Samways 1994b) and the discovery of these habitats and hence the species has meant that the status of the latter on the *Red List* has been altered from 'Endangered' to 'Rare'. This is not a general rule, however, because other South African damselflies are not only highly localized but also extremely rare.

3.3.1.3 A phylogenetic perspective

Patterns of endemism are central to vicariance or cladistic biogeography, a method that seeks to correlate phylogenetic patterns of monophyletic lineages with historical events (Nelson and Platnick 1981; Humphries and Parenti 1986). Many studies have focused on global patterns, and relationships have been sought among continent-wide areas of endemism (e.g. Crowe and Crowe 1982; Cracraft 1991). Increasingly, research is being carried out at a smaller spatial scale, with the areas of endemism defined by cladistic analyses corresponding to centres of local endemism, which are of much interest to conservation biologists (Platnick 1991; Samways 1992b).

Endemism is a topic around which historical biogeographers, conservation biologists and ecologists can interact meaningfully. Phylogenetic biogeographers can contribute significantly by determining sequences of speciation events, while ecologists and conservation biologists can supply the detailed ecological and palaeoecological information required to interpret the processes involved and the role of particular ecological scenarios in provoking endemism *per se*.

3.3.1.4 Biases

Endemism is influenced by taxonomic interpretation, sampling error and human perceptions of rarity. Of particular importance is the fact that limited geographical exploration, as well as variation in the application of taxonomic concepts, introduces biases in the identification of endemics and in the significance of their status (Kruckeberg and Rabinowitz 1985). Inadequate or uneven surveys may lead to the recognition of 'pseudoendemism', simply because the full geographic range of the taxon has not been sampled (Nelson *et al.* 1990). Pseudoendemism can be artefacts of excessive taxonomic splitting, and are 'lost' if taxa are aggregated into polytypic forms (Crowe *et al.* 1994). Pseudoendemism can also result when a large tract of a species' habitat is removed, thereby reducing its present geographical range. Habitat loss, on the other hand, may also result in the extinction of local endemics before they have been collected (Gentry 1992).

Different value systems and socioeconomic conditions introduce obvious biases into how endemic taxa are perceived in society. For example, in the biodiversity-depauperate but wealthy United Kingdom, extinction of the endemic subspecies of the large copper butterfly (*Lycaena dispar dispar*) stimulated a major re-establishment programme of the Netherlands subspecies (*L. dispar batava*; Duffey 1977). Such attention would be most unusual in many poorer but biologically richer countries in the tropics and in temperate areas of the southern hemisphere, unless the subject taxon was unusually charismatic or of national, regional or international importance.

3.3.2 Evaluating endemism

In quantifying patterns of endemism, the units of measurement (spatial scale and taxonomic entity) and the mode of reporting of the data (percentages or counts) influence the interpretation of results. Many studies on levels of endemism are insufficiently explicit about the evaluation methods employed. It is important to be unambiguous about defining and categorizing endemism, especially since it is often used as a criterion for identifying and prioritizing protected taxa and areas. Here, a clarification of the problems and approaches in the evaluation of endemism is proposed.

3.3.2.1 Units of measurement

Determining whether a species is endemic depends on the spatial scale of the host area (point locality, region, state, province, country, subcontinent, island, etc.) (Major 1988). Almost inevitably, larger centres of endemism have within them smaller centres, for example those for plants in New Caledonia (Gentry 1992). Range sizes for defining local endemism of species endemic to a given geographical area are often arbitrarily set. For example, Terborgh and Winter (1982), Gentry (1986) and ICBP (1992) define local endemics (birds and plants) to be those with geographical ranges of less than 50 000 km². In contrast, Cowling and Holmes (1992) set the geographical range limit for locally endemic plants in the Cape Floristic Region of South Africa as 2 000 km², a size that is appropriate for a region with a high concentration of both plant and insect (Samways 1994a) point endemics.

Bykov (1983) developed a quantitative index of higher plant endemism based on the linear relationship between percentage endemism (on a log scale) and the logarithm of land area (Figure 3.3-1). The line is defined at its upper end by 100% endemism for the Earth, and at its lower end by 1% endemism in 625 km². The latter value is arbitrary (considerably higher and lower values have been reported in the literature), although the precise slope of the line is little influenced by changes in endemism values over the range of 300 km² to a few thousand km². A quantitative index is $le = Ef/En$ where le is the index of endemism, Ef is the factual percentage of endemism, and En is the normal percentage of endemism, read off the line in Figure 3.3-1. A value of $le = 1$ indicates normal levels of endemism (e.g. Austria, Guinea, Libya and the United States in Figure 3.3-1); a value of below 1 (above the line) indicates less than average endemism (Burkina Faso, Denmark, Ireland and Niger); and a value of above 1 (below the line) indicates greater than average endemism (e.g. Australia, New Caledonia, New Zealand and South Africa). Bykov's index is the only quantitative measure of endemism available, although Major (1988) warns against its exclusive use as there may be a dearth of appropriate knowledge on taxonomy or ranges.

The endemic taxa of different regions can be evaluated on a continuous scale of range size when calculated as the sum of the inverse range sizes of all taxa in each quadrat (cell grid or map unit). There are several applications of this measure in the recent literature (e.g. Howard 1991; Williams 1993; Williams *et al.* 1994), although such analyses are not exclusive of endemism.

Evaluation of endemics must also consider the mobility of the taxa under consideration (Samways 1993a). Crowe and Brooke (1993), for example, point out that the 50 000 km² criterion employed by ICBP (1992) for identifying endemic birds disqualifies endemic species from arid areas because they are often, of necessity, highly mobile and

may, at any given time, occupy ranges of less than 50 000 km². This example is a good illustration of the need to distinguish between extent of occurrence and area of occupancy (Gaston 1991).

From all perspectives – ecological, biogeographical and conservation – patterns of endemism are best studied in relation to ecologically homogeneous, biogeographic areas (Major 1988). However, it will often be expedient to use a political unit such as country, state, municipality or reserve, as the geographic unit of reference, as this may be the most effective decision-making unit for the preservation of endemics. Ultimately, the unit used will be influenced by the questions posed for a particular investigation.

Patterns of endemism can also be influenced by the taxonomic or phylogenetic scale employed. For example, if the units of endemism are low-ranking taxa (subspecies or closely related species), centres with many such taxa, such as Lake Malawi with its array of recently evolved and genetically similar cichlid fish species (Ribbink *et al.* 1983; Meyer 1993), will feature prominently. However, if the units of endemism are high-ranking taxa, which

Figure 3.3-1: Bykov's (1983) nomogram for determining average endemism. Points above the diagonal line have lower than average endemism, points below have more (see text for details). Data are percentage plant endemism in the countries of the world (from WCMC 1992). Some countries have been labelled to highlight patterns.

tend to be less speciose but more distinct genetically, key areas may shift quite markedly, e.g. from Malawi to eastern Madagascar for cichlids (Stiassny and de Pinna 1994; see also Vane-Wright *et al.* 1991; Nixon and Wheeler 1992).

There are no hard-and-fast rules relating to selection of spatial and taxonomic units. Appropriate scales will be determined by the available and potential databases, the nature of the study areas, and the research question posed. Ideally, data should be collected (and presented) at several scales, thus enabling comparisons to be made among taxa for congruence in patterns of endemism (see 3.3.3.3).

3.3.2.2 Percentages versus counts

Endemism may be expressed as a percentage of all extant taxa present (excluding exotics), or as the absolute number of endemics in the area. Depicting plant endemics in biogeographic regions as percentages or counts, using area and latitude as explanatory variables, results in very different patterns (Figure 3.3-2) with different significance. Ideally, both measures of endemism should be given. The percentage approach has powerful imagery in that it emphasizes the generality of endemism in a biota, regardless of the total number of endemics. Counts of endemics become most significant when total richness and propensity for endemism are high. Geographically old islands, such as Madagascar for example, may have high proportionate endemism, even for relatively mobile animals. Acridoid grasshoppers are about 94% endemic in Madagascar, but in mainland South Africa they are only about 47% endemic at the species level (Samways 1994b). Some areas, such as oceanic islands and arid regions, although low in actual number of endemics, may support a high percentage of endemic taxa (Briggs 1966; Bramwell 1979; Clancey 1986; Gentry 1992; WCMC 1992; Cowling and Hilton-Taylor 1994). For example, the entire indigenous flora of 46 species, including many interesting high-ranking taxa (Cronk 1987), is endemic to the tiny oceanic island of St Helena. Such an island is a 'flagship area' for endemic plant species conservation, and the St Helena flora is currently subject to a concerted conservation effort. Continental 'flagship areas' are also evident in some parts of the world – e.g. the Tepuis of Venezuela, the Itombwe–Kahuzie area of upper Zaire and the Udzungwa Scarp in Tanzania (Dinesen *et al.* 1993), and the Cape Peninsula of South Africa (Picker and Samways 1995).

3.3.3 Patterns

Many different approaches are used for identifying patterns of endemism, but all require accurate distributional data or maps of uniformly identified taxa as the basic units in the analysis. Good distributional and well-resolved taxonomic data are lacking for most taxa, particularly in the tropics.

Nonetheless, many centres of endemism have been identified for a wide range of organisms at different spatial scales (e.g. Crowe and Crowe 1982; Terborgh and Winter 1982; Gentry 1986; ICBP 1992; WCMC 1992; Cowling and Hilton-Taylor 1994).

3.3.3.1 Centres of endemism

Endemics are not randomly distributed across the Earth but tend to be clustered. This section outlines some of the problems in identifying these centres and indicates some misconceptions about their location. It does not discuss the delimitation and distribution of the many centres that have been identified. Also discussed are the problems of identification, and also the opportunities for conservation, of congruent patterns of endemism.

Regarding the size and distribution of centres of endemism, the view is widely held that high latitude regions support fewer and larger geographical centres than the lower latitudes (e.g. Rapoport 1982; Gentry 1986; Major 1988; Stevens 1989; WCMC 1992). There are, however, numerous exceptions to this pattern, particularly in the temperate and subantarctic zones of the southern hemisphere (Hopper 1979; Santelices 1989; Given 1990; Cowling *et al.* 1992; Platnick 1992; Samways 1992a; Arroyo *et al.* 1995b). Furthermore, most centres have been identified on the basis of endemic flowering plant floras and large-bodied terrestrial vertebrate faunas. These biases (taxonomic, tropical vs temperate, and terrestrial vs marine) have the potential to distort patterns of endemism, with significant consequences for conservation interventions (Given 1990; Redford *et al.* 1990; Platnick 1991; Samways 1993b).

3.3.3.2 Other patterns

At a global scale, the degree of endemism in many groups of organisms increases with decreasing latitude (Gentry 1986; Major 1988; Stevens 1989; Figure 3.3-2). However, very high endemism of terrestrial taxa is recorded in the mid-latitudes of the southern hemisphere, particularly in, and adjacent to, areas with Mediterranean-type climates (Hopper 1979; Cody 1986; Cowling *et al.* 1992; Platnick 1992; Cowling and Hilton-Taylor 1994). The lowest levels are recorded in high latitude, Northern Hemisphere areas which were glaciated during the Pleistocene (Major 1988; WCMC 1992; Samways 1994a).

Range sizes of freshwater fish in North America and Europe increase only above a latitude of 40° N, and marine teleost fishes have smaller range sizes at higher latitudes than at lower latitudes (Rohde *et al.* 1993).

Centres of endemism for marine algae are concentrated in mid-latitude areas with the highest percentage of endemics recorded along the temperate southern Australian coast (Lunig 1990; Groombridge 1993). Briggs (1966, 1969) demonstrated that the percentage of endemic nearshore invertebrates is low around northern temperate

Figure 3.3-2: Relationships between two measures of endemism (percentages and counts) and area and latitude for plant in 52 biogeographic units in tropical and subtropical forest and savanna (●), temperate forest and woodland (○), mediterranean-climate shrubland and woodland (▲), warm desert and steppe (■), cold desert and steppe (□), and boreal and forest and tundra (▽) on continental land masses across the globe. Data from Major (1988), Myers (1988, 1990) and Cowling and Hilton-Taylor (1994).

islands and increases steadily southwards, peaking in the subantarctic. He attributes the low endemism in the northern islands to higher levels of extinction during the Quaternary.

3.3.3.3 Congruence

Overlapping or congruent distribution patterns for different taxa have been used extensively by biogeographers to reconstruct historical events (e.g. Nelson and Platnick 1981; Prance 1982; Cracraft and Prum 1988; Cracraft 1991). Patterns of congruence of endemism play a crucial role in identifying conservation areas that will maximize

the preservation of different biotas (Vane-Wright *et al.* 1991; Table 3.3-1). Congruence may be related to fundamental ecological requirements of, say, mutualists, rather than coincidences of occurrence. For example, there is tight coupling between mutualist endemic orchids of Madagascar (*Angraecum* spp.) with their long nectary spurs and the pollinator hawkmoths with their equally long proboscises (Nilsson 1988).

Critical faunas analysis applied to swallowtail butterflies (Collins and Morris 1985) and to tiger beetles (Pearson and Cassola 1992) indicates distinct patterns of congruence of endemic species among these taxa in seven countries

Table 3.3-1: Critical swallowtail faunas (CSFs) (after Collins and Morris 1985) and critical tiger beetle faunas (CTBFs) (after Pearson and Cassola 1992) for the first 10 countries for each insect assemblage. (From Samways 1994a.)

(Samways 1994a; Table 3.3-1). These countries are clear flagships for unique biotas. There is also considerable congruence at a global scale between centres of endemism for birds, mammals and amphibians (Cracraft 1991; ICBP 1992). However, only 61 of the 221 Endemic Bird Areas recognized by ICBP (1992) overlap with the 246 Centres of Plant Diversity recognized by Davis *et al.* (1994–5), although it must be pointed out that different criteria were used to identify these areas. For birds, a standardized set of criteria was used, whereas the centres defined for plants were based on a combination of criteria and were the consensus of experts.

At a regional scale, patterns are highly variable among different taxa and in different regions (e.g. Rodgers and Homewood 1982; Crowe 1990; Thomas 1991; Groombridge 1993; Prendergast *et al.* 1993) and no generalizations have emerged. In isolated biotopes such as certain oceanic islands, caves and tropical mountain peaks, patterns of endemism are often congruent across many taxa (Schafer 1990; Groombridge 1993) but no such patterns exist on some islands (WCMC 1992; Holloway 1993) and on serpentine outcrops in California (Kruckeberg 1992).

The identification of patterns of congruence is extremely sensitive to spatial scale and taxonomic hierarchy (Samways 1993b). Congruence is likely to be most elusive in small quadrats because of small differences in biotope preference and mobilities from one species to another, and even from one life-history stage to another (Prendergast *et al.* 1993; Samways 1993b). There should be some attempt to standardize research protocols for analysing patterns of

endemism in different taxa, particularly within the same biogeographic zone or political entity. Lack of strong congruence in patterns underlines the fact that endemism is an expression of many different causes, of which geographical isolation is but one. However, until methods are more standardized it will be difficult to evaluate the true contribution of causal factors to these different patterns.

3.3.4 Endemism: correlates and causes

The causes of endemism are complex and numerous, and include historical processes, contemporary ecological factors, inherent biological properties of taxa and their combinations. In many cases, historical factors may be more important than the ecological determinants, resulting in poor relationships between measures of endemism and explanatory variables reflecting the contemporary environment (e.g. Endrody-Younga 1988; Machado 1992). Establishing correlates is a useful step towards understanding the causes and patterns of endemism. In other words, when compared to more widespread taxa, are narrow endemics a random subset of the biota with regard to abiotic and biotic factors? Despite the importance of identifying the correlates and causes of endemism for biodiversity conservation (Lawton 1993; McDonald and Cowling 1994; Samways 1994a) very few data exist, and these are largely confined to higher plants, although information does also exist for southern African insects (Samways 1994a). Relevant data for plants are reviewed in Kruckeberg and Rabinowitz (1985) and Major (1988).

3.3.4.1 Regional species richness

Regional or landscape-level species richness is a product of three independent diversity components: alpha diversity (the numbers of species in a homogeneous community), beta diversity (the degree of compositional change along biotopes gradients), and gamma diversity (the degree of compositional change between similar biotopes along geographical gradients) (see Section 2.3.2.1, Box 2.3-1). Landscapes with high numbers of biotope-specific or stenotopic endemics (high beta diversity), and many ecologically equivalent species restricted to geographically disjunct portions of the same ecosystem (high gamma diversity), are often species-rich (Cody 1986; Cowling *et al.* 1992). Thus, a correlation between species (and generic or family level) richness and degree of endemism may be evident in some cases (Figure 3.3-3; Major 1988; Stevens 1989; Williams *et al.* 1994). Where centres of endemism are also centres of diversity, then potential conflict between the goals of protecting richness versus restricted range species (Margules *et al.* 1982) may be lessened. Gentry (1992), however, has stated that for neotropical plants, patterns of endemism and diversity are largely non-coincident, suggesting that major centres of diversity (e.g. Mittermeier and Werner 1990) give an inadequate representation of neotropical plant diversity (see also Platnick 1991). For southern African dragonflies and terrestrial vertebrates, the most species-rich area is the warm and sub-humid eastern region, yet most endemics (and threatened taxa) occur in the temperate southwestern Cape region (Samways 1992b; 1994b; Siegfried and Brown 1992). Similarly, in the tropical Andes, areas with high concentrations of both low- and high-ranking bird endemics do not necessarily have the highest species richness (Fjeldsa 1994). For further discussion of this topic see also 3.2.1.2.4.

3.3.4.2 Area

Proportionate levels of endemism increase with increasing geographical area (Major 1988). For flowering plants, there is a positive relationship between endemism (expressed both as counts and as percentages) and the size of large ecologically homogeneous areas (Major 1988, Figure 3.3-2). Inevitably, endemics also decline per unit area with increasing taxonomic level. Studies must, therefore, be explicit about their location and taxonomic level (e.g. Vane-Wright and Pegg 1995) and the sampling intensity. On a small scale, the number of edaphic endemics confined to limestone and serpentine outcrops declines with decreasing areas of these biotopes (Cowling and Bond 1991; Kruckeberg 1992, respectively). Because of the importance of area size in determining levels of endemism in different taxa, it should always be included as an explanatory variable when patterns of diversity are being modelled (cf. Wright 1983).

3.3.4.3 Environmental factors

Levels of endemism may vary in a predictable way along gradients of primary environmental variables such as rainfall, temperature and productivity. Theoretically, models that accurately predict levels of endemism on the basis of easily measurable environmental variables should be useful for the rapid identification of endemic-rich areas (e.g. Hill and Keddy 1992). However, few such models exist, and tests on them show mixed results (e.g. Santelices and Abbott 1987; Santelices 1992).

There are indications that at a global scale, plant endemism is positively correlated with productivity (Major 1988), although high levels of endemism have been recorded in many warm and cold desert areas (Stebbins and Major 1965; Quezel 1978; Major 1988; Cowling and Hilton-Taylor 1994; Squeo *et al.* 1994). Levels of higher plant endemism tend to increase with increasing average elevation (reflecting increased habitat diversity and isolation of mountain tops in most cases) and with higher rain-fall in low- and mid-latitude regions including tropical rain forest areas (Ashton and Gunatilleke 1987; Gentry 1986, 1992), middle Asia (Major 1988), the Mediterranean Basin (Strid 1986) and the Cape Floristic Region (Cowling 1983; McDonald and Cowling 1994). In the Cape and southwestern Australia there is evidence of a negative correlation between soil fertility and endemism (Cowling *et al.* 1992, 1995). In the California Floristic Province, high-ranking (and presumably ancient) endemics are clustered in the driest and wettest (refugial) sites, whereas low-ranking, and presumably younger, endemics occur in ecotones where rates of speciation are high (Stebbins and Major 1965). Preliminary data for African birds (e.g. Clancey 1986; Crowe *et al.* 1992) indicate a similar pattern, as do those for certain butterflies in the neotropics (Brown 1991). In the Mediterranean area of central Chile, endemic

Figure 3.3-3: Relationship between species richness and percentage endemism for 52 biogeographic units on continental land masses across the globe. Data and sources are the same as those in Figure 3.3-2.

genera tend to cluster in the equitable coastal areas (Arroyo *et al.* 1995a).

The incidence of endemism for a wide range of marine organisms tends to be more pronounced in exposed and variable nearshore environments than in distant-shore environments. Taxa showing this pattern include littoral gastropods in Hawaii (Kay 1967), Brazil and Ghana (Vermeij 1972); cephalaspid opisthobranch gastropods in the northwest Atlantic (Franz 1970); deep-sea chaetognaths and fishes (David 1963); and Brazilian scleractinian corals and gorgonians (Vermeij 1972).

3.3.4.4 Biotope

Geographically isolated areas and biotopes (*sensu* van Tol and Verdonk 1988) such as certain islands, mountain peaks, ancient lakes, caves, thermal vents, hot springs, vernal pools, the abyssal zone and chemically imbalanced substrates support a disproportionately high number of stenotopic endemics. Patterns and causes of endemism are well studied for some taxa in certain biotopes (e.g. higher plants and vertebrates on islands and mountain tops) but for others such as thermal vents and the abyssal zone, only preliminary species lists are available (Grassle *et al.* 1985; Grassle and Maciolek 1992). Although the costs and time to survey many of these unusual and inaccessible biotopes are often prohibitive, there is an urgent need for predictive models of levels of endemism in these areas, so as to ascertain appropriate protection of these biotope types. Likewise, understanding the causes of endemism in these unusual habitats could shed much light on evolutionary processes in general.

Plant endemism on islands has been much studied (e.g. Hooker 1867; Valentine 1972; Carlquist 1974; Bramwell 1979) and is well documented (WCMC 1992). Generally, larger continental islands such as Madagascar, New Caledonia and New Zealand, along with those islands whose geological history has provided the conditions conducive to the evolution of high beta and gamma diversities (e.g. Hawaii and the Juan Fernández Islands), support the greatest number of endemic plant taxa (Carlquist 1974; Bramwell 1979; WCMC 1992). However, there are few empirical models that predict the number of endemic taxa on islands in terms of variables such as area, latitude, elevational range, productivity, isolation and age. There are positive correlations between elevational range and endemism for plants in the Canary Islands (Cain 1944; Humphries 1979), and for birds in Indian Ocean archipelagos (Adler 1994), suggesting the importance of topographical diversity in promoting endemism on islands. Because of their requirement for long-distance dispersal on younger, oceanic islands and an ability to persist on older, continental islands, island endemics are likely to differ from continental endemics in their biological attributes (Carlquist 1974; Ehrendorfer 1979). Carabid beetles, for

example, tend to show wing atrophy on islands and mountains (Kavanaugh 1985). Some plant groups have undergone extensive and unusual adaptive radiation on oceanic islands such as the Canaries (Humphries 1979) and Hawaii (Robichaux *et al.* 1990), while continental islands such as Crete, Madagascar and New Caledonia are typically rich in ancient, high-ranking taxa endemics (Greuter 1972; Gibby 1979; Guédès 1979; Davis *et al.* 1994; Williams *et al.* 1994).

Mountains are also often rich in endemics, in both tropical and temperate countries (Hedberg 1969; Maguire 1970; Valentine 1972; Crowe and Crowe 1982; Rodgers and Homewood 1982; Gentry 1986; Kruckeberg and Rabinowitz 1985; Strid 1986; Lovett 1988; Major 1988; Samways 1992a; Matthews *et al.* 1993; Williams 1993; McDonald and Cowling 1994). Many desert inselbergs act as mesic refugia that support endemics: this is particularly pronounced for plants in middle Asia (Major 1988) and the Sahara (Quézel 1978). Similarly, southern African mountain peaks are refugia for grasshoppers avoiding winter cold-air drainage (Samways 1990). In high latitude montane areas of the northern hemisphere, which were once heavily glaciated, levels of plant endemism are low (Major 1988).

The restriction of endemic plant species to nutritionally imbalanced substrates (e.g. serpentine, limestone, quartzite) is a widespread phenomenon in endemic-rich areas such as New Caledonia and the Mediterranean Basin (Papanicolaou *et al.* 1983), California (Kruckeberg 1969, 1992; Raven and Axelrod 1978), southwestern Australia (Hopper 1979; Cowling *et al.* 1995), southwestern Cape of South Africa (Cowling *et al.* 1992), New Zealand (Given 1981), and neotropical rain forest regions (Gentry 1986, 1992; Brown and Prance 1987). There is much evidence to suggest that these nutritionally unusual substrates provide a strong selective force for the evolution of plant endemics (Raven 1964; Bradshaw and McNeilly 1981; Kruckeberg 1986; MacNair 1987). These sites also provide a refuge from competition for ancient, high-ranking endemics (Zedler *et al.* 1984; Major 1988). The restriction of animal taxa to unusual substrates has not been studied in any detail (Kruckeberg 1992). However, the checkerspot butterfly *Euphydrya editha*, which is restricted to ultramafic outcrops in the San Francisco area, is attracted by the microclimate afforded by the more open, serpentine vegetation rather than the nutritional peculiarities of the plants that grow there (Johnson *et al.* 1968).

3.3.4.5 Biological factors

Are biological factors such as body size, growth form, life history traits, population size, relative age, absolute age, genetic architecture, etc. reflected in range size or area of occupation, or are these factors random with respect to spatial variation? There are few explicit studies on the biological aspects of endemism involving more than a few

species and some of these studies strictly pertain more to rarity (Fiedler 1986; Howden 1985; Cowling *et al.* 1992; Cowling and Hilton-Taylor 1994; McDonald and Cowling 1994; Cowling *et al.* 1995; see also Kruckeberg and Rabinowitz 1985; Major 1988).

In the nutrient-poor and Mediterranean-climate environments of South Africa and southwestern Australia, endemics in fire-prone shrublands are significantly over-represented among low to medium-height shrubs (Cowling *et al.* 1992, 1995; McDonald and Cowling 1994). Non-graminoid herbs are over-represented in the endemic floras of California (Raven and Axelrod 1978), the uplands of southeastern Africa (Cowling and Hilton-Taylor 1994), serpentine outcrops of western North America (Kruckeberg 1992), and the granite outcrops of southwestern Australia (Ordin 1987 in Kruckeberg 1992). Gigantism is a common feature among certain plant groups endemic to alpine habitats at low latitudes (e.g. Hedberg 1969). Among neotropical forest plants, endemic taxa tend to be herbs, shrubs or epiphytes rather than forest trees (Gentry 1992), whereas in the rain forests of Sri Lanka, endemics are mainly long-lived, late successional trees (Gunatilleke and Ashton 1987). In southern African semi-arid shrublands, dwarf succulent shrubs and geophytes are significantly over-represented among endemics (Cowling and Hilton-Taylor 1994).

Among animals, gigantism, dwarfism and flightlessness are widespread among island endemics (Thaler 1973; Lawlor 1982), as well as among continental narrow-range endemics, especially when these are confined to historically insular biotopes. For example, dung beetles (Scarabaeinae) endemic to the Chiriqui area of Panama and to the Caribbean islands are significantly smaller than the average for Central and South America (Howden 1985). Beetles endemic to the Florida sand hills do not show a reduction in size but many are flightless, as is the case with true island forms. With very few exceptions, the narrow-range endemic damselflies of South Africa are larger and less vagile than wider-ranging species (Samways 1994b).

The reproductive correlates of endemism have been more extensively studied than other biological characteristics. Kunin and Gaston (1993) review studies which have shown that endemic *Paramecium* species, plants, carabids and rodents (*Peromyscus* spp.) have lower levels of self-incompatibility, a greater tendency toward asexual reproduction, lower overall reproductive effort and poorer dispersal abilities than widespread species in the same groups (see also Kruckeberg and Rabinowitz 1985). Relative to widespread species, the odds are significantly in favour of local plant endemics in the Cape Floristic Region of South Africa being fire-sensitive, having low reproductive output, having myrmecochorous seeds with short dispersal distances, and maintaining small and weakly persistent seed banks, thus rendering them prone to fire-

induced population reduction (Cowling *et al.* 1992; McDonald and Cowling 1994). The Californian chaparral shrub genera *Arctostaphylos* and *Ceanothus*, which comprise the bulk of the narrow endemic shrubs in this vegetation (Cody 1986), are also predominantly fire-sensitive (Wells 1969). Included among the predominantly herbaceous endemic flora of the Californian Floristic Province are many species of *Clarkia*. These have transient seed banks, and are vulnerable to local extinction or severe population reduction as a result of environmentally extreme events (Lewis 1962). In the neotropics, Gentry (1988, 1992) found that wind-dispersed species of Bignoniaceae have broad geographical ranges while animal-dispersed species tend to be more narrowly distributed. Renner (1990) found a similar pattern for neotropical Melastomataceae.

Few studies have addressed whether plant endemics are a non-random assemblage with regard to pollination vectors. Cowling *et al.* (1992) found that insect-pollinated species were over-represented (but not significantly so) relative to wind- and bird-pollinated species among local endemics in a flora from the Cape Floristic Region. Endemic plant species with deep corolla tubes may have either specialist endemic (Nilsson 1988) or widespread (Johnson and Bond 1994) insect pollinators.

The generalization exists that range size and population size are positively (albeit weakly, $R = 0.41$) correlated (Lawton 1993; see also Willis 1922; Gaston and Lawton 1990). Point or local endemics best fit the notion of rarity, but not all endemics, particularly those confined to larger areas, are rare (Kruckeberg and Rabinowitz 1985). It is important to categorize endemics on the basis of population size, since locally endemic stenotopes with small population sizes are extinction-prone (Terborgh 1974; Gentry 1991; Rebelo 1992; Samways 1994b). No generalizations can be made at this stage with regard to other demographic correlates of endemism, at least for higher plants (Kruckeberg and Rabinowitz 1985; Major 1988).

Many studies indicate that plant and animal endemics have lower levels of genetic variation in comparison with widespread species (Stebbins 1942; Babbel and Selander 1974; Moran and Hopper 1983; Loveless and Hamrick 1984; Prentice 1984; Kruckeberg and Rabinowitz 1985; Grant and Little 1992; Sherman-Broyles *et al.* 1992). This may be due to several factors including adaptation to narrow ecological conditions (Van Valen 1965), low population size (Gottlieb 1974), genetic bottlenecks (Gottlieb 1979) and self-compatibility in plants (Jain 1976; Kruckeberg and Rabinowitz 1985; Karron 1989). However, there are cases of little difference in genetic diversity between endemic and widespread plant species (e.g. Babbel and Selander 1974; Ledig and Cronkle 1983). Although genetic studies can be useful in illuminating the nature and origin of endemics (Major 1988, Hamrick *et al.* 1991), as

well as providing guidelines for their preservation (Moran and Hopper 1983), more research is required, particularly in endemic-rich tropical rain forests, for valid generalizations to emerge.

There are very few studies on the physiological attributes of endemic species (Baskauf and Eickmeir 1994; Synder *et al.* 1994). Other than the propensity of plant edaphic endemics to tolerate extraordinary accumulations of heavy metals, and to cope with extreme levels of certain soil nutrients (e.g. Wild and Bradshaw 1977; Papanicolaou *et al.* 1983), no generalizations regarding plants are possible at this stage.

3.3.4.6 Taxonomic correlates

At a regional level, there is evidence that endemic biotas are not a random assemblage phylogenetically. Some plant families are over-represented and others under-represented in centres of endemism in southern Africa (Cowling *et al.* 1992; Cowling and Hilton-Taylor 1994; McDonald and Cowling 1994), southwestern Australia (Cowling *et al.* 1995), western North America (Raven and Axelrod 1978; Kruckeberg 1992), northern Europe (Major 1988), Eurasia (Major 1988) and the neotropics (Gentry 1986). The same applies to dragonfly families in southern Africa (Samways 1992b). Global-scale generalizations are not particularly relevant, since patterns depend on the available genetic stock, which varies regionally. Nonetheless, there appears to be a trend for graminoid lineages such as the Poaceae and Cyperaceae to be under-represented as endemics in many floras across the globe. In both southwestern Australia and the Cape Floristic Region of South Africa, the Proteaceae and the closely-related Epacridaceae/ Ericaceae lineages are disproportionately rich in endemics (Cowling *et al.* 1995).

The existence of discernible phylogenetic correlates of endemism implies that range size may be an evolutionarily stable character of a lineage (Ricklefs and Latham 1992; Lawton 1993). Thus, the characteristics of a species may be the cause rather than the consequence of restricted geographical range (Vrba 1980; Cowling and Holmes 1992; Kunin and Gaston 1993). Species belonging to these lineages may be 'pre-adapted' to cope in small population sizes and might well persist in the face of habitat fragmentation (Lawton 1993). This seems to be the case for fire-sensitive shrubs with poor dispersal and low reproductive output, which are significantly over-represented among point endemics in South Africa's Cape Floristic Region (Cowling and Bond 1991).

3.3.4.7 Modelling

Because of the high costs of carrying out biological inventories (Raven and Wilson 1992), it is important that the correlates of endemism are modelled so that surveys of taxa whose systematics are well understood can be taken to

the level of hypothesis testing. Consideration should be given to the use of explanatory variables which are quickly and inexpensively quantified or qualified, thus enabling the rapid development and testing of model predictions (Peters 1992). The correlates of endemism are numerous and complex, resulting in many co-linearities and higher order interactions. Simple correlations and two-way contingency tables will seldom prove adequate. Since the response variable is likely to have an error distribution that is either binomial (e.g. proportion of endemics) or Poisson (e.g. counts of endemics with many zero values) and the explanatory variables are often factors (e.g. growth form, habitat type), traditional multiple regression analyses will seldom be appropriate. Logistic regression (Crawley 1993; Trexler and Travis 1993) and other generalized linear models hold much promise for these kinds of data sets.

3.3.4.8 Endemism and reserve selection

The distributions of endemic taxa are often used to identify areas for protection (e.g. Terborgh and Winter 1983; Ackery and Vane-Wright 1984; Collins and Morris 1985; Conservation International 1991; ICBP 1992; Saetersdal *et al.* 1993). Quantitative approaches to reserve selection are now well developed, and a selection of iterative algorithms using the principle of complementarity is in use (Pressey *et al.* 1993; Forey *et al.* 1994). The 'critical faunas' approach of Ackery and Vane-Wright (1984; see also Collins and Morris 1985, Pearson and Cassola 1992), is based on counts of endemic species in political entities. However, Vane-Wright *et al.* (1991) point out that critical faunas analysis, which is based solely on endemics, does not offer a sufficiently flexible conservation strategy at the global level. In addition to numbers of endemics, scoring systems for sites should include a factual evaluation of threats, appropriate measures of site viability, species richness, and consideration of cladograms which provide hypotheses on the genetic diversity of the taxa to be conserved (e.g. Williams *et al.* 1993; Williams and Humphries 1994).

3.3.5 Special conservation considerations

This subchapter summarizes the scientific generalizations and questions that have emerged from this review of endemism and which are relevant to the conservation and preservation of biodiversity. The first question examined is that of how endemic taxa can be used as tools for conservation, and this is followed by consideration of some of the special conservation needs of endemic taxa.

3.3.5.1 Endemic taxa as tools in conservation

As endemics, by definition, are organisms with restricted geographical ranges, they are useful for developing conservation priorities. Several applications are pertinent.

1. Endemic taxa have been excellent for identifying genetically rich areas for biodiversity conservation (Myers 1988, 1990; New and Collins 1991; Bibby *et al.* 1992; Rebelo and Siegfried 1992), particularly when used alongside taxonomic measures and also in conjunction with complementarity of biotas (Williams and Humphries 1994). Endemic-rich areas can correspond with centres that are generally rich in species, particularly at the larger spatial scale, and for ecosystems such as Mediterranean-climate shrublands, tropical forests and coral reefs. However, at the smaller scale of localities, sites or biotopes, and in arid ecosystems, there may be a high percentage of endemism but low species richness. More research is required to elucidate these patterns. Endemic taxa and levels of endemism have played an important role in the debate on world species richness (e.g. Erwin 1988; Grassle and Maciolek 1992; Stork 1993).
 2. Location and conservation of centres of high levels of endemism apparently may, in some regions, become an umbrella for the conservation of more common, widespread and eurytopic species. This point requires research, and must not ignore other approaches such as conservation for 'typicalness' or 'representativeness', and for organisms whose appearance and abundance is a function of the stage of plant succession (Usher 1986; Usher and Jefferson 1991).
 3. Abrupt changes in the spatial distribution of endemic taxa indicate steep ecological gradients and a diversity of biotopes (Cowling *et al.* 1992), features that are often desirable in a protected area (Graham 1988; Hunter *et al.* 1988).
 4. Endemic taxa may indicate past Tertiary or Quaternary refugia. This is seen in Amazonia where endemic centres for heliconiine and ithomiine butterflies correlate strongly with geological evidence for persistence of tropical forests (Brown 1991). African (Crowe and Crowe 1982) and South American (Haffer 1969; Cracraft and Prum 1988) narrowly endemic birds also indicate past refugia.
 5. Endemics can sometimes be sensitive indicators of anthropogenic disturbance (Moolman and Cowling 1994; Samways 1994b). The early settlers of the Hawaiian islands appear to have been responsible for the loss of 50 of the 100 endemic bird species up to the late eighteenth century, while at least another 13, especially within the Meliphagidae, have become extinct since then (Groombridge 1993). Indeed, across the Pacific islands in general as many as two-thirds of the birds may have been exterminated by humans (Pimm 1995). Although less than 20% of the Earth's avifauna is restricted to islands, more than 90% of the extinctions during historic times have occurred on islands and all have been direct or indirect consequences of human activity (Olsen 1989; Johnson and Stattersfield 1990). However, relating endemics to type and degree of disturbance is a complex matter, and relates to the particular taxon under consideration.
 6. Certain charismatic endemic organisms have considerable ecotourism value. They may also be national symbols, as with the New Caledonian Kagu (*Rhynochetos jubatus*), the New Zealand Kiwi (*Apteryx australis*) and the Chilean copihue (*Lapageria rosea*).
- 3.3.5.2 *Pointers in the conservation of endemic taxa*
- Certain facets are especially relevant to the conservation of endemics.
1. Areas with unusually high numbers of endemics need to be identified. These areas may not only be large-scale (biogeographical regions, political entities, countries, etc.), but may also be more localized (certain landscapes, biotopes, etc.). The value of these areas may not necessarily be only in the high number of low-ranking taxa, but also in the value of unusual high-ranking taxa (e.g. Fjeldsa 1994). Habitat destruction in such areas is a critical issue because, unlike more widespread species, these taxa are not replaceable from elsewhere.
 2. There is an urgent need to model the abiotic and biotic correlates of endemism in many areas and for many taxa. The models can be used to predict the location of endemic-rich areas and to identify the biological characteristics of endemics requiring special management procedures (Gilfedder and Kirkpatrick 1993; McDonald and Cowling 1994). Certain endemic taxa may not be able to survive on their own, and may depend on endemic mutualists. Conditions, therefore, must suit the interaction as well as the taxon *per se*.
 3. As the centres of endemism for different taxa often do not coincide, one taxon may not be an exact umbrella for other taxa. This may be the case within higher taxa as well as among them. Nevertheless, certain geographical centres may embrace a wide range of endemic taxa and these should be identified as a matter of priority. Much more research is required on taxic congruence at the regional and higher levels (e.g. Williams and Humphries 1994) and sub-regional levels (Samways 1993c).

4. Although there is generally a strong argument to preserve large tracts of land or sea, small reserves may be highly significant for certain taxa, especially where anthropogenic pressures are strong and the endemic component includes many naturally rare taxa (Terborgh 1974; Cowling and Bond 1991; Gentry 1992). The Cape Peninsula of South Africa is a prime example: more than 200 plant species, most of them rare habitat specialists (Hall and Veldhuis 1985) and 112 species of invertebrates (Picker and Samways 1995) are endemic to a rapidly urbanizing area of less than 500 km² (Rebelo 1992). As endemics are often stenotopic and susceptible to disturbance, it may be necessary to buffer these small reserves with multiple-use zones.
5. Endemic species are often highly sensitive to the impact of exotic invasives, both plant and animal. In the Cape Floristic Region of South Africa, alien invasive species are the largest threat to the 1326 *Red Data Book* plant taxa that are endemic there (Rebelo 1992). The Nile perch *Lates niloticus* and the Nile tilapia *Oreochromis niloticus* have been responsible for the decline and total disappearance of numerous endemic cichlids from Lake Victoria and Lake Kyoga in East Africa (Barel *et al.* 1985; Ogutu-Ohwayo 1990). In New Zealand, the stilbocarpa weevil *Hadramphus stilbocarpace* survives only on rat-free islands (Howarth and Ramsay 1991). In South Africa, the minute remaining single population of the butterfly *Orachrysops ariadne* is threatened not only by populations of alien trees but also by the exclusion of megaherbivores which formerly maintained this butterfly's habitat (Samways 1994a). The introduced land snail *Euglandia rosea* has been directly responsible for the extinction of several dozens of species of *Partula* and *Achatinella* in Hawaii and the Society Islands (Cowie 1992).
6. Endemics are also recognized as being particularly susceptible to possible adverse effects of biological control programmes (Samways 1994a). There must therefore be a continual awareness and vigilance of the impact of alien invasives on endemics. This not only requires research, but also practical considerations such as stricter quarantine.
7. Endemics may have special management requirements, especially if they are highly stenotopic (McDonald and Cowling 1994). Where many endemics occur in one area and conservation funds are limited, the best umbrella management option is to conserve the whole landscape in its perceived pristine state (Hunter *et al.* 1988). Such a state may not be static. Highly localized disturbances such as tree falls, or larger-scale processes such as browsing by elephants (*Loxodonta africana*),

occasional flooding, landslips etc., should also be recognized or even introduced. This would maintain short- and long-term plant successional processes which may be crucial for the conservation of endemics.

8. The *Red List* is an important flagship for the conservation of endemic taxa that are known to be threatened by humans (Groombridge 1993). Of the current 5925 listed animal species, 71% are confined to only one country. The *Red List* is therefore an important document for the conservation of endemics. Research should aim to update this publication continually.
9. Following from point (8), the ongoing development of new criteria for listing species on the IUCN *Red List* (Mace *et al.* 1992; Mace 1993) is especially relevant to endemics, and research should aim at establishing the validity of these test criteria for the preservation of endemics.

EXECUTIVE SUMMARY

Section 4 addresses all of the questions related to the basic dynamics of biodiversity: that is, the mechanisms of its creation, its maintenance and its alteration, including loss. The main findings of this assessment, and the major knowledge gaps identified, are as follows.

History of biodiversity

- The fossil record provides rich data on biodiversity through the history of life.
- The fossil record reveals that most species are rather ephemeral and that more than 95% of species that ever existed are now extinct.
- Mean life-span of fossil species, based on mammals and marine invertebrates, varies by an order of magnitude, from one million years to 10 million years.
- Rebounds from mass extinctions are geologically rapid but ecologically slow, and the recovery of biodiversity and re-establishment of some communities typically require 5–10 million years.
- Background extinction patterns, as deduced from the fossil record, are potential sources of insight regarding present-day losses of biodiversity.
- Evidence from the most recent part of the fossil record will be the best for understanding how biodiversity responds to changing environmental and biotic conditions.

Genetic diversification

- Genetic diversity within a species is important for understanding biodiversity for two reasons: (1) the potential of a species to respond to environmental change depends on the extent of diversity and the kind of diversity that is present, and (2) current patterns of genetic diversity can provide important clues to the history of a species and to its current population structure.
- Commonly used measures of genetic diversity are based on a small sample of loci, usually fewer than 100 loci out of the tens of thousands that are thought to be important in higher organisms. It is as yet unknown to what extent this sample is representative of the genome as a whole.
- A knowledge gap exists in identifying genetic variation in loci that are important for adaptive evolution.

- The processes that govern the evolution of allele frequencies are well known, but we know little about how these processes act together in maintaining diversity in each species.
- Small population size increases the rate of loss of genetic diversity. Strong reduction in population size can result in significant reduction in viability or fertility (inbreeding depression), especially in outcrossing species.
- It is not possible to predict the response of natural populations to a major change in the environment. Although artificial selection experiments have shown a potential for rapid genetic response in most traits of most species, a species can react to environmental change in ways that do not require genetic evolution, for example by changing its habitat or geographic range, or by going extinct.
- Different populations of the same species may be adapted to different ecological conditions. Ignoring those differences, some of which drastically inhibit interbreeding, can have undesirable and immediate consequences.
- New genetic tools are discovered on a regular basis and hold promise for increased understanding and improved management of present and future diversity at the genetic and population level.

Speciation

- The formation of new species occurs by a number of different mechanisms whose importance varies between taxonomic groups. Whatever the mechanism, three points about speciation are generally applicable: (1) it begins with an existing species, (2) it is associated with genetic change, and (3) it has a strong ecological context.
- Speciation occurs along two possible paths: (1) a gradual change of an entire lineage, or (2) the branching of a lineage into two separate lineages.
- Allopatric (geographic) speciation, where populations diverge while spatially separated, is regarded as the most common mode of speciation in animals.
- Parapatric speciation, where adjacent populations diverge, and sympatric speciation, where divergence occurs without spatial separation, are possible modes of speciation but their importance is controversial.

- Speciation by polyploidization is common among plants, where many species are the result of chromosome duplication in hybrids between two other species.
- Rapid multiplication of species has occurred several times in the history of life, and in widely different taxa. Rapid speciation may be associated with the evolution of key structures (key innovations), or with the occupation of vacant niches, but these explanations must still be regarded as tentative.
- The phenomenon of speciation teaches us that conservation of biodiversity must include conservation of the evolutionary processes that generate and maintain diversity.

Ecology of extinctions

- Documented extinctions since 1600 amount to 484 animal species and 654 plant species. These numbers are certainly underestimates of the actual number of extinctions.
- Current and past extinction rates can best be compared by estimating the life-span of an average species in well-known taxa; for mammals, it is (of the order of) 1 million years based on the fossil record, 10 000 years based on documented extinctions during the last century, and 100 to 1000 years based on recent species-by-species assessments of extinction risk.
- Current and future extinction rates have been estimated indirectly from the relationship between the size of an area and how many species it holds. Recent rates of deforestation of 1% per annum translate into rates of extinction of about 0.25% per annum (this should be interpreted as the fraction of species eventually going extinct according to the species–area relationship).
- It is clear that even if the above-mentioned numbers should be regarded as only crude estimates, current extinction rates are dramatically higher than background extinction rates.
- For every species that goes extinct, many populations have become extinct (termed local extinction or extirpation). Particularly well documented cases of local extinction come from the British Isles and the Netherlands. In the latter, 2–24% of the species in well-known taxa such as butterflies, birds and mammals are now nationally extinct.
- Mechanisms of extinction, i.e. those factors that explain why populations go extinct under prevailing environmental conditions, include negative (population) growth rate, demographic stochasticity due to randomness in births and deaths, environmental stochasticity due to climatic and other external variability, and genetic factors.

- Small populations have a high risk of extinction, whatever the cause of their small size, and whatever the relative importance of the various mechanisms of extinction.
- Factors important to single populations apply to groups of populations (metapopulations) as well. In addition, metapopulation extinction depends on stochasticity in local colonization and extinction rates, and on the degree of spatial correlation of environmental conditions.
- Causes of extinction, i.e. those factors that make populations vulnerable to extinction in the first place, include habitat degradation (loss, change in quality and fragmentation), over-exploitation and persecution, and introductions of alien species. All of these factors may have been important in the extinction of 2000 species of birds (20% of the total number of bird species) on oceanic islands, following the arrival of humans on those islands.
- Quantitative prediction of extinction risk (termed Population Viability Analysis) must be based on the known mechanisms of extinction and detailed information about the focal species.

Dynamics at the community and ecosystem level

- Biodiversity cannot be properly understood without due consideration of its dynamics in communities and ecosystems. Interactions among species play an essential role in the generation and maintenance of biodiversity.
- No single factor can account for the whole structure and species diversity of communities. Abiotic factors, biological interactions such as competition, predation, parasitism and mutualism, and their various indirect effects, ecosystem processes, temporal and spatial variability of the environment, regional processes and historical contingency, and evolutionary processes, all have to be taken into account to varying degrees to explain the diversity of species in any local community or region.
- Interspecific competition tends to limit the number of coexisting species on an ecological time-scale, but also to increase niche differentiation among species, and thus to diversify species' traits on an evolutionary time-scale. Although predation has direct negative effects on the prey consumed, it can also be a powerful factor enhancing prey species diversity.
- Many species are important to others not because they feed upon them or are fed upon by them, but because they provide their physical habitat, modify their physical habitat or provide them with diverse benefits such as protection or dispersal (various mutualists).

- The continued interactions among organisms are not only responsible to a significant extent for the maintenance of biodiversity, but also for its evolutionary generation. The coevolution of species tends to produce novel biological traits. It is likely to be particularly important in host–associate systems, where it can take the form of co-speciation.
 - Spatial heterogeneity and temporal variability of the environment are also major factors determining the maintenance of biodiversity in communities and ecosystems. Environmental heterogeneity allows potentially more species to coexist, and may be especially important in the maintenance of the diversity of plants and other sessile organisms. Temporal fluctuations of the environment also increases the potential for coexistence of species.
 - Our ability to predict the long-term consequences of species losses or introductions on existing communities is still limited due to the manifold potential indirect interactions among species. This commands caution in attempts to manage biodiversity.
 - The rich complexity of both the physical environment and the interactions among organisms and species appears to be crucial for the maintenance and generation of biodiversity. Thus, the ecosystem and its component communities appear to be very appropriate targets for conservation, because they take into account explicitly the many ecological interactions between organisms and their biotic and abiotic natural environment. A space-orientated approach up to the landscape scale may be the most appropriate tool with which to conserve the vast majority of biological diversity.
-

4.0 Introduction

Understanding the natural dynamics of biodiversity at all levels from genes to ecosystems is essential for evaluating the impact of humans on this diversity. This Section outlines the processes and mechanisms that govern the generation, maintenance and loss of biodiversity. Our perspective is a broad one: over 3.5 billion years of life, millions of species, the genetic uniqueness of virtually every individual, and the ecological interactions between individuals within and among species. Yet, this multitude of life-forms can be understood in the light of a single unifying concept – the theory of evolution. This theory holds that organisms now living have descended with modification from common ancestors, and that the mechanisms (if not always the underlying causes) that brought about changes in the past, operate today and therefore can be studied experimentally (e.g. Dobzhansky 1970; Futuyma 1986).

It is not our purpose to review here the theory of evolution. Rather, we present those aspects of it that are relevant for understanding the current biodiversity crisis. In Section 4, we focus on living beings (biota) whereas Sections 5 and 6 include the abiotic environment in their focus on ecosystems. Collectively, Sections 4, 5 and 6 provide a framework for understanding the magnitude, patterns and trends in biodiversity as they are outlined in Sections 2 and 3. Moreover, they lay a foundation for evaluating how human action influences biodiversity, both by threatening it (Section 11) and by conserving it or sustainably using its components (Sections 10 and 13).

Section 4 was initially planned as part of the DIVERSITAS programme of IUBS, UNESCO and SCOPE (Solbrig 1991). In its current form it is a joint contribution of GBA and DIVERSITAS. The section is divided into five chapters, each addressing one of the following questions relevant to the dynamics of biodiversity: (1) What does the history of life on Earth teach us about future biodiversity? (2) What are the mechanisms of genetic change and what is the role of genetic diversity in determining the ecological and evolutionary potential of species? (3) What processes lead to the formation of new species? (4) What do we know about extinction rates and about the mechanisms and underlying causes that bring about extinction? (5) How far do the dynamics and future of biodiversity depend on the community and ecosystem structure in which it exists?

Chapter 4.1 reviews some of what is known about ancient biodiversity, from the recesses of deep time in the Precambrian microbial world to the rapid ecological shifts witnessed by pre-literate humans. It begins with a general consideration of the quality of the fossil record. Then, it briefly summarizes current knowledge of the historical development of taxonomic richness among various components of the Earth's biota. This is followed by a very

brief review of ancient pulses of extinction and their consequences for victims and survivors. Finally, it ends with considerations of the most recent and best-resolved portion of the fossil record, which illustrates how the biota reacted to important geological and climatic changes.

Chapter 4.2 focuses on the contribution of population genetics to understanding biodiversity. The chapter describes measures of genetic diversity for different levels of genetic variation, and outlines the processes that govern this diversity within and between populations. The point is made that although our knowledge of basic population genetic processes is good, we know little about how these processes interact to maintain genetic diversity, especially as it relates to adaptive evolution. This limits the possibility of predicting the response of a species to environmental change.

Chapter 4.3 outlines the processes that lead to the formation of new species, and examines the evolutionary diversification of species. Building on the various species concepts described in Section 2, and on the processes of genetic diversification described in Chapter 4.2, this chapter discusses why different modes of speciation prevail in different taxa, and why some modes of speciation are still controversial. The chapter concludes by highlighting the role of evolutionary processes in conservation thinking.

Chapter 4.4 compares extinction rates in the past with estimates for the present and predictions for the future. Whatever the method used, the projected rates for the near future are extremely high compared with the natural background. The chapter outlines the reasons why small populations are more vulnerable to extinction than large ones, and presents a summary of the causes that make populations small in the first place. Finally, the chapter describes how theoretical and empirical knowledge about target species can be combined to assess their future risk of extinction.

Chapter 4.5 highlights the community and ecosystem framework that forms the basis of the origin, maintenance and loss of diversity at lower levels. The dynamics and future of biodiversity rely (in a similar manner to the traits of species) on selective pressures applied by elements of the ecosystem, including habitat structure, food species, predators, parasites, mutualist species and diseases. The chapter introduces some of the processes that are further discussed in Sections 5 and 6 and examines the role of interspecific biological interactions in the origin and maintenance of biodiversity, including evolutionary aspects. It outlines the reasons why spatial heterogeneity and temporal variability of the environment are also major factors determining biodiversity in communities and ecosystems. Finally, the chapter emphasizes how crucial for the dynamics of biodiversity are the rich complexity of the physical environment and the interactions among organisms and species. It concludes that ecosystems and

their component communities are very appropriate targets for biodiversity conservation.

4.1 Large-scale history of biodiversity

4.1.1 Introduction

The fossil record is the principal archive of ancient biodiversity. Together with morphological and genetic relationships among living species, molecular clocks, and modern biogeographic distributions, the fossil record permits historical reconstruction of the origins of modern biodiversity. The record also reveals biotic events that could never be deduced from the living biota alone, such as vast evolutionary radiations and mass extinctions.

The fossil record also reveals that most species are rather ephemeral and that more than 95% of species that ever existed are now extinct (Raup 1991a). The average animal species in the oceans has a duration of approximately 4 million years (Ma) (Raup 1991b). This is an incredibly long time by human cultural standards but remarkably short in comparison to the nearly 4000 Ma history of life on Earth. A 4 Ma duration means that roughly 25% of marine species become extinct each million years. If it is assumed that this figure is general to all ecosystems, and that the Earth harbours over 107 species, then, on average, two to three species world-wide should become extinct each year from natural processes. The fossil record shows, however, that there is a huge variance about this simple average, with long quiet intervals, when the net amount of biodiversity accumulated, and pulses of extinction, when the net amount of biodiversity declined.

4.1.2 The nature of the fossil record

4.1.2.1 General considerations

The usual fossil is a bit of shell, an impression of a leaf, or an isolated tooth weathered from some geological stratum. Each provides evidence as to the identity and distribution of some ancient organism. The evidence is fragmentary, lacking details of the complete anatomy, behaviour, physiology, genetics or abundance of the species. The usual fossil is not a soft-bodied annelid, a lightly skeletalized copepod, or a mountain-dwelling herb. These kinds of organisms, with comparatively few exceptions, are lost to biological and physical processes of decay and rock formation. Thus, the fossil record is very incomplete in its capture of ancient biodiversity, a fact recognized by Darwin (1859) in two of his longest chapters in *On the Origin of Species*.

In recent decades there have been interesting efforts to measure the incompleteness of the fossil record, for both global biotas and specific taxa, and to develop numerical methods to accommodate this incompleteness. Estimates of incompleteness of global biotas involve counts of the number of described fossil species and educated guesses as

to how many species must have existed over geological time. For the marine fauna, Raup (1976) counted 190 000 fossil invertebrate species listed in the *Zoological Record* up to 1970. The actual number of described fossil marine animal species is now probably somewhere between 250 000 and 300 000, accommodating newly described species (especially from Asia), marine vertebrates, and older species overlooked by the *Zoological Record*.

Estimating how many animal species ever lived in the oceans involves four kinds of numbers: (1) how many species are alive today; (2) the age of the oldest fossil animal; (3) the average geological duration of species; and (4) the trajectory of diversity increase over time. All of these numbers presently have considerable uncertainty, but some rough figures are available. Recent estimates of modern animal diversity in the oceans place the figure at about 245 000+ (Winston 1992; see also Briggs 1994). Redating of the Proterozoic–Cambrian boundary at 545 Ma (Bowring *et al.* 1993) and discovery of primitive Ediacaran-type fossils associated with late Varangerian glacial tillites (Narbonne and Hofmann 1987) leads to an estimate of roughly 600 Ma for the age of the oldest animal species. As discussed above, the estimated average duration of a species is about 4 Ma. The fourth estimate needed, the history of marine species diversity, is the most uncertain (e.g. Signor 1990), but it has been suggested that despite the ups and downs of marine biodiversity through the Phanerozoic (see 4.1.3.1), a straight-line interpolation between 600 and 0 Ma might not accumulate too much error (Sepkoski 1992a). Thus, the rough estimate of the total number of animal species that ever lived becomes the area of a triangle measured in units of 4 Ma:

$$1/2 \times 245\,000 \text{ species} \times 600 \text{ Ma} / 4 \text{ Ma} = 18\,375\,000 \pm \text{species.}$$

4.1.2.2 Estimating fossil biodiversity with higher taxa

The sample of species from most of the fossil record may be small and biased, but palaeontologists have recognized that higher taxa in the traditional Linnaean hierarchy might provide better reflections of the history of taxonomic biodiversity (e.g. Simpson 1953; Newell 1967; Valentine 1969; Raup 1979a; Sepkoski 1992a). The reasoning is simple: there are fewer genera, families and so on than species and therefore the sampling of one species documents the occurrence of a genus, family and so on. Thus, the known record of supraspecific taxa must be more complete and less biased than the 2% sample for fossil species. This approach has recently been embraced by some conservation biologists (e.g. Gaston and Williams 1993; Prance 1994; Williams and Gaston 1994; Gaston *et al.* 1995) who are advocating use of higher taxa to identify ‘hotspots’ of modern local biodiversity.

The use of higher taxa begs the question of whether the diversity of genera, families, etc. erected by systematists

co-varies with the richness of species. The problem is that Linnaean supraspecific taxa have often been delineated arbitrarily, vary greatly in size, and frequently differ from modern phylogenetic concepts of holophyletic clades.

Palaeontologists have offered three arguments in support of using traditional Linnaean taxa to study underlying species richness. The first is that in the modern world the diversity of supraspecific taxa frequently parallels that of species, among islands, continents and latitudinal zones (e.g. Stehli *et al.* 1967; Flessa 1975; Jablonski and Flessa 1986). The second is that measures of taxonomic richness in the oceans are co-parallel, no matter how they are measured: local taxonomic richness of recognized species (alpha diversity) correlates highly with global species, genus and family diversity (Sepkoski *et al.* 1981).

The final argument for why traditional higher taxa might adequately reflect underlying species patterns of diversification has involved computer modelling. Some palaeontologists have developed virtual phylogenies governed by reasonable rates of evolution and plausible modes of sampling. Sepkoski and Kendrick (1993) did this in response to arguments by Patterson and Smith (1987, 1989) that arbitrarily defined taxa (i.e. non-holophyletic) could not accurately reflect geological patterns of extinction and, by supposition, taxonomic diversity among species (Smith 1994). Sepkoski and Kendrick's models suggested that arbitrary, paraphyletic groups of highly variable membership can indeed adequately reflect underlying patterns of species richness under many patterns of diversification and sampling. Thus, the published consensus seems to be that patterns of taxonomic diversity compiled from local fossil sites and from compilations of taxa from the palaeontological literature reflect something of the true large-scale history of biodiversity.

4.1.3 History of biodiversity

The best-documented history of change and maintenance of biodiversity is for marine animals. This is because the marine fossil record is more complete (seas accumulate sediment whereas land tends to erode); temporal correlation and therefore macro-evolutionary pattern are better controlled; and more marine fossil species have been studied than fossil terrestrial species (Raup 1976; although see Benton and Simms 1995).

4.1.3.1 Animal diversity in the oceans

Figure 4.1-1 illustrates the known diversity history of marine animal families counted at the geological standard of international stratigraphic stages. Three phases of diversification are evident. The first is the Cambrian phase, which actually encompasses two phenomena: an explosive radiation in the Early Cambrian (during which most animal phyla appeared; e.g. Conway Morris 1993) and then a stabilization of familial diversity through the Middle and

Late Cambrian. The ensuing Palaeozoic phase of diversification encompasses a larger, tripling of familial richness during the Ordovician and then a stabilization of marine diversity for nearly a quarter of a billion years (except for several events of mass extinction and subsequent rebound). This phase in the history of marine diversity is ended by the end-Permian mass extinction and is followed by an almost steady increase in familial diversity through the Mesozoic and Cenozoic Eras except, again, for several mass extinctions. This increase is not constant, however, but seems to be tapering through time (Sepkoski 1984; see also Benton 1995), suggesting an approach toward a plateau similar to the short-lived stabilization of the Cambrian and the longer plateau of the later Palaeozoic (see 4.1.5.1).

It is interesting to note that the three phases of marine diversification were not contributed to equally by all animal groups that arose in the great Cambrian explosion. Rather, the Cambrian phase of radiation was contributed by taxonomic groups often viewed as archaic, such as trilobite arthropods, inarticulate brachiopods, hyoliths (possibly related to sipunculids and/or molluscs; see Runnegar *et al.* 1975), and primitive echinoderms (Guensburg and Sprinkle 1992). Most of these animals played little role in the Ordovician radiations. The Palaeozoic interval of diversification was a function of radiation of the sessile benthos: articulate brachiopods, crinoids, tabulate and rugose corals, and the stenolomate bryozoans. These groups (other than the last) appeared during the Cambrian but did not expand appreciably until the Ordovician; they underwent massive radiation and then dominated most marine ecological communities until the end of the Permian Period. The modern animals that live on present-day oceanic continental shelves, such as bivalves, gastropods, shrimps and crabs, sea urchins, and marine vertebrates, are responsible for the final phase of Phanerozoic marine diversification. This final diversification more than doubled taxonomic richness in the Cenozoic oceans over levels experienced during the Palaeozoic.

The Cambrian marine fauna consisted largely of generalized detritus-feeders and low suspension-feeders; they had low alpha (community-level) diversity (Bambach 1977) and evidently low beta (between-community) diversity, suggesting rather low levels of ecological specialization. The Cambrian fauna was replaced during the Ordovician Period by more diverse epifaunal suspension-feeders that seem to have been more ecologically specialized; Sepkoski (1988) measured beta diversity for Palaeozoic benthic animals and found a major increase in habitat specialization associated specifically with the Ordovician radiation, and not repeated with later Palaeozoic changes. The rise of the Modern evolutionary fauna is associated with the 'Mesozoic Marine Revolution', which involves the evolutionary expansion of shell-

Figure 4.1-1: Diversity of marine animal families through 77 time intervals of the Phanerozoic. The heavy upper curve shows the total number of families with skeletalized species known from the fossil record, with the principal phases of diversification indicated at the top. The fields below the upper curve show the contributions of the three great evolutionary faunas (Cm = Cambrian Fauna; Pz = Palaeozoic fauna; Md = Modern fauna). Some of the major classes are listed for each fauna. Arrows mark the five major mass extinctions of the marine realm: P = end-Permian (the largest); 1 = end-Ordovician; 2 = Late Devonian; 3 = end-Triassic; 4 = end-Cretaceous. (From Sepkoski 1992.)

breaking predators (Vermeij 1977, 1987) and disruptive sediment movers (Thayer 1983), which could have destroyed the stable bottom environment of the Palaeozoic sessile benthos.

There are two modes of explanation for the ‘stair-step’ pattern of increase in taxonomic richness and replacement of evolutionary faunas. One is that it is a response to various extrinsic factors that might enhance marine biodiversity, and the other that it is an intrinsic response of the biota itself. Extrinsic explanations vary. For example, Valentine (1971) argued that the Mesozoic–Cenozoic increase in marine biodiversity reflects the break-up of the supercontinent Pangaea and increasing climatic differentiation during the Cenozoic. These factors would enhance longitudinal and latitudinal endemism respectively, leading to greater global diversity (see also Cracraft 1985, 1992). More recently, Bambach (1993) has argued that the

expanding diversity from the early Palaeozoic to the Cenozoic is a marine response to increased nutrient runoff from land: early colonization by land plants in the Ordovician and Silurian led to enhanced transport of nutrient-rich organic material down rivers to the oceans, allowing more marine species to coexist, and then rapid radiation of angiosperms into far more terrestrial habitats during the Cretaceous further enhanced the food supply for marine animals. Vermeij (1995) speculates further that geological intervals of major volcanism, associated with continental break-up and oceanic spreading, injected higher than usual levels of inorganic nutrients into ocean waters, which again permitted more species of animals to coexist.

Intrinsic explanations of the historical pattern of diversity increase in the oceans examine the evolutionary potential of the succeeding evolutionary faunas. Sepkoski (1984, 1991) has argued that different groups of major taxa

(i.e. taxonomic classes) have different characteristic rates of diversification and levels of 'equilibrium' (see also Kitchell and Carr 1985). These rates and 'equilibrium' relate to how finely the species subdivide environmental resources, with clades comprising characteristically very generalized species having high rates of evolution but low species-level carrying capacities, and clades of ecologically specialized species having lower rates of evolution (it is more difficult to find a specialized resource) but higher species-level carrying capacities (more species can inhabit a finely subdivided habitat). Evidence for this view is that (1) taxa among the successive marine evolutionary faunas seem to exploit more and more ecological means of making a living (Bambach 1983); (2) taxa seem to live in more parts of the benthic environment, both above and below the sediment–water interface, through the Phanerozoic (Bottjer and Ausich 1986); and (3) the empirical differences in rates of evolution and levels of diversity can be used as parameters in rather simple models that lead to parsimonious quantitative descriptions of faunal and diversity change through the marine Phanerozoic (Sepkoski 1984, 1991; Kitchell and Carr 1985).

4.1.3.2 Pre-animal biodiversity in the oceans

Animals appear in the fossil record nearly 85% of the way down the recorded history of life on this planet. The oldest fossils are currently dated at about 3550 Ma (Awramik *et al.* 1983). These fossils represent bacteria and perhaps even aerobic photosynthesizers (J.W. Schopf and Packer 1987). However, this earliest fossil record is sparse and still very poorly understood (J.W. Schopf 1992a). It is not until the Middle Proterozoic, beginning about 1800 Ma, that adequate fossils occur so that a record of global biodiversity can be assembled.

The occurrence of 'acritarchs' at about 1800 Ma provides a benchmark for the initial diversification of eukaryotic organisms. Acritarchs are refractory sporopollenin fossils larger in diameter than most prokaryotes and are interpreted as life-cycle stages of unknown groups of eukaryotic organisms (e.g. Knoll 1994). Knoll (1994) has summarized the known record of pre-Phanerozoic acritarch diversity and has shown that there was little diversification of these eukaryotes prior to 1000 Ma at either the local or global ecological scales. This date corresponds approximately to both an increase in the complexity of fossils found in the record, such as brown, green and chromophytic algae, and a growth in the taxonomic diversity of complexly ornamented, and thus differentiated, acritarchs. Knoll (1992) argues that this explosion in the fossil record is not inconsistent with current estimates from molecular phylogenies (Sogin *et al.* 1989) of a rapid divergence of eukaryotes with haplo-diploid sexuality late in the Proterozoic.

Thus, like the Phanerozoic fossil record, the Proterozoic record exhibits a pattern of jumps and bounds in taxonomic

diversity, perhaps related more to evolutionary innovation than to physical change. Once eukaryotic organisms became diverse, mass extinctions become empirically obvious in the fossil record (although J.W. Schopf (1992b) argues for a long-term decrease in microbial diversity starting around 1000 Ma and lasting until the Cambrian). There appear to be two mass extinctions among acritarchs in the Late Proterozoic, after about 700 Ma (Knoll 1994). The first is a decline associated with the widespread Varangerian glaciations, predating most metazoan fossils (see also Vidal and Knoll 1982). This was evidently followed by a rapid evolutionary rebound to even higher levels of planktonic diversity just below the widespread Ediacaran animals (Knoll 1994). A second crash ensued, followed by possible extinction of the Ediacaran animals (Seilacher 1989). In the earliest Cambrian, planktonic acritarchs again rebounded to much higher levels of diversity and with much higher rates of evolutionary turnover. Sepkoski (1992b) and Knoll (1994) rationalize this change as a response to ecological linkage of planktonic photosynthesizers with newly evolved benthic animal consumers.

4.1.3.3 Plant diversity on land

The terrestrial ecosystem seems to have lagged behind the oceans in colonization by complex organisms, despite a long history of eukaryotic photosynthesizers in the oceans. There is scant evidence of terrestrial photosynthesizers at perhaps 1000 Ma (Horodyski and Knauth 1994), but evidence of true land plants dates only from the mid-Ordovician at about 460 Ma (Gray 1985), more than 100 Ma after the emergence of metazoan animals in the oceans. This earliest history is represented by trilete spores of the kind produced by terrestrial plants. It is not for another 50 Ma, in the Late Silurian, that the fossil record yields plant tissues that can be definitively attributed to vascular plants (e.g. Niklas *et al.* 1985; Behrensmeyer *et al.* 1992).

The first important diversification of land plants began in the Early Devonian, with rapid evolution from ground-hugging rhizomatous plants to forest canopy forms. With mature ecosystem structure, land plants thereafter diversified in leaps and bounds, much like animals in the oceans, with different 'evolutionary floras' becoming successively dominant (Niklas *et al.* 1983; Knoll 1986; Figure 4.1-2a). There was increased taxonomic diversity in the Carboniferous with the expansion of arborescent lycopods and pteridosperms; a small, but perceptible, increase in global diversity in the early Mesozoic ('Mesophytic') with ascendancy of the gymnosperms; and then a substantial and rapid increase in global plant diversity with the appearance and radiation of the angiosperms during the Early and Middle Cretaceous (Niklas *et al.* 1985; Lidgard and Crane 1988). These global

Figure 4.1-2: Land plant diversity through the Phanerozoic (Silurian to Tertiary). (a) Global species diversity (compiled mostly from Europe and North America). The upper heavy curve indicates total diversity, with fields below showing contributions of four evolutionary floras: 1 = primitive vascular plants; 2 = pteridophytes and lycopsids; 3 = gymnosperms; 4 = angiosperms. (b) Average alpha diversity of land plants (mean number of species per fossil flora). The local pattern is similar to the global pattern except that there is no increase in local diversity in the transition from evolutionary flora 2 to 3. The dashed line indicates the expected pattern had subtropical fossil flora been sampled, as in preceding intervals. (a) after Niklas *et al.* 1985; (b) from Knoll 1986.

changes are largely reflected in community-level increases in diversity (Figure 4.1-2b; Knoll 1986). Local fossil assemblages become much more diverse as pteridosperms radiate in the Early Carboniferous and especially as angiosperms expand in the mid-Cretaceous. Most data suggest that angiosperms are continuing their expansion toward the present day (Figure 4.1-2), although taxonomic precision and geographical sampling do not yet offer precise assessment.

Most explanations for this stepwise increase in the diversity of tracheophytes involve intrinsic evolutionary

breakthroughs. Niklas *et al.* (1985), for example, stress the reproductive differences among the various evolutionary floras and how reproductive innovations could have enhanced global floral diversity.

4.1.3.4 Terrestrial arthropods

Arthropods are now the most diverse group of animals on Earth (May 1988), and their major terrestrial components are insects and arachnids. Mites (Arachnida) may have moved on to land very early, virtually contemporaneously with the earliest land plants (Retallack 1985). However, the fossil record of arachnids is sparse, and little is known about the evolution of their terrestrial biodiversity (see Behrensmeyer *et al.* 1992).

Insects appear in the fossil record in the Early Devonian (Labandeira *et al.* 1988) during the time of the initial diversification of land plants. The early record of insects is sparse, but by the Late Carboniferous numerous taxa of winged insects existed. Labandeira and Sepkoski (1993) and Jarzembowski and Ross (1993) have summarized the fossil record of insect families and have noted two major trends. First, insects of the Palaeozoic, including cockroaches and dragonflies, seem to have attained roughly stable diversities (Fig. 4.1-3) with much higher rates of turnover (i.e. extinction) than later insect groups. The Palaeozoic cohort appears to have suffered greatly at the end-Permian mass extinction, with approximately two-thirds of insect families becoming extinct. If the same calculations made by Raup (1979b) for the marine fauna apply, then much more than his 96% extinction of marine animals would apply to insects. This appears to be the only great extinction in the history of insects.

Figure 4.1-3: Diversity of insect families through the Phanerozoic (Devonian to Pleistocene). Although familial diversity appears to rise almost steadily, there is a major turnover, and probably a mass extinction, between the Permian (P) and Triassic (Tr). Sporadic, extremely rapid increases in diversity thereafter are artifacts of extremely good preservation, including the Jurassic lake deposits of Karatau and mid-Tertiary Baltic ambers. (Modified from Labandeira and Sepkoski 1993.)

Following the end-Palaeozoic, insects expanded greatly, probably up to the present day. This long-term expansion involved surviving groups from the Palaeozoic, such as the beetles and true bugs, as well as newly appearing clades, such as the moths and butterflies and the wasps, ants and bees (which include social insects). Interestingly, global insect diversity in the fossil record exhibits no response to the rapid expansion of angiosperms in the mid-Cretaceous and, if anything, exhibits a slowdown (but not cessation) of radiation. Reasons for this are not clear, but Labandeira and Sepkoski (1993) speculate that insects might have been approaching ecological saturation even before angiosperms spread, not unlike what is seen among Palaeozoic marine animals. Vermeij (1995) and others, however, question whether diversity counted at the level of insect families could resolve such a question.

4.1.3.5 Terrestrial tetrapod vertebrates

Tetrapod vertebrates – boned animals with four limbs – appear in the fossil record in the Upper Devonian, after the first phase of land plant and terrestrial arthropod diversification. The earliest tetrapods evidently were largely aquatic animals (Coates and Clack 1991), and many continued to be so through the succeeding Carboniferous Period (Ahlberg and Milner 1994). However, the Carboniferous witnessed the evolution of various solely terrestrial insectivorous tetrapods, including the first amniotes – those vertebrates capable of reproducing independently of water (Behrensmeyer *et al.* 1992). At an early time in this evolution, the synapsid line (eventually giving rise to mammals) separated from other tetrapods.

The evolution of taxonomic diversity among tetrapods is inadequately known. Terrestrial fossil deposits are unevenly preserved in time, with the Middle Jurassic especially poorly preserved (Benton 1987, 1988), and also in geographical distribution, with, for example, the very latest Cretaceous dinosaurs known definitely only from western North America (Dodson and Tatarinov 1990) and, perhaps, China. Thus, current diversity curves could represent as much barometers of current knowledge as measures of evolutionary diversity.

Benton (1985, 1989) has provided the best recent assessment of current knowledge of tetrapod taxonomic diversity (Figure 4.1-4a). His family-level data exhibit three ‘assemblages’ of tetrapods through time, not unlike the evolutionary faunas in the oceans. There is (1) low diversity in the mid- to Late Palaeozoic, involving mostly non-amniotic tetrapods; (2) probably higher diversity (but poorly preserved) in the Mesozoic, involving amniotic dinosaurs, pterosaurs and other diapsids; and (3) nearly an order of magnitude higher global diversity during the Cenozoic, contributed by mammals and birds. Benton (1990) has also collected numbers of fossilized species in well-preserved local faunas throughout the tetrapod fossil

Figure 4.1-4: Diversity of tetrapod vertebrates through the Phanerozoic (Devonian to Pleistocene). (a) Global numbers of families. The upper curve shows the total number of families recognized throughout the world. Fields below indicate contributions from three, somewhat arbitrary ‘evolutionary assemblages’: I = labyrinthodont amphibians, non-turtle anapsids and mammal-like reptiles; II = early diapsids, pterosaurs and dinosaurs; III = lissamphibians, lizards, snakes, crocodiles, birds and mammals. The minimum in diversity over the Jurassic is an artefact of poor global preservation. (b) Mean and maximum local diversities, based on 100 well-sampled fossil tetrapod faunas. Local richness avoids some of the biases of global taxonomic diversity and exhibits increase in the Jurassic with the ascendancy of evolutionary assemblage II. It also exhibits a far smaller increase in the Tertiary with the expansion of assemblage III, perhaps because local richness is largely independent of provinciality and vicariance. (a) from Benton 1985; (b) from Benton 1990.

record (Figure 4.1-4b). These numbers exhibit a far smaller increase in tetrapod diversity between the Mesozoic and Cenozoic Eras. Maximum local species diversity in the Jurassic was as high as at any time, and average local diversity preserved in Cenozoic faunas was less than twice that of the middle and late Mesozoic. This suggests that the great increase in global tetrapod diversity during the

Cenozoic may have been a result of (1) the dispersal of continents with the break-up of Pangaea (consider the distinctiveness of the Australian marsupial fauna); and/or (2) enhancement of the equator-to-pole climatic gradient (consider the distinctiveness of modern tropical and temperate faunas).

4.1.4 Extinction through time

4.1.4.1 Background extinction

There is no significant geological interval in which some taxon below the ordinal level has not become extinct (Raup and Sepkoski 1982). Indeed, the calculations offered in 4.1.1 would suggest that as much as a quarter of Earth's species become extinct each million years. The reasons for this are unknown. Explanations range from Darwin's (1859) ideas concerning interspecific competition, to more recent attribution to climate change (e.g. Stanley 1988; Vermeij 1989), and to accumulation of deleterious genes as a result of inbreeding (e.g. Jimenez *et al.* 1994). No good protocol has yet been offered to distinguish between these different possibilities, largely because detailed observations in the fossil record are few, and time scales are long by human standards.

Some descriptive aspects of the history of background extinction have been documented, however. It seems that background rates have decreased over time among many higher eukaryotes (Figure 4.1-5). Marine animals seem to be less vulnerable to extinction now than during the Palaeozoic (Raup and Sepkoski 1982) as do some terrestrial tetrapods (Valentine *et al.* 1991). However, extinction rates among eukaryotic plankton (Knoll 1994) and land plants (Niklas *et al.* 1985) seem to have increased over time. Explanations for declines in specific systems have been of two kinds. One is that individuals within species have become progressively more fit over the geological eons so that species as a whole today are more resistant to extinction (e.g. Raup and Sepkoski 1982). The other, which has more empirical evidence, is that extinction resistance is a shared quality among species in a clade (Jablonski 1987) and that clades with extinction-prone species tend to disappear more rapidly than clades whose species are resistant to extinction (for whatever reason, such as wider geographical distribution; cf. Jablonski 1986a, b, 1991). Thus, a general decline in background extinction is an epiphenomenon of disappearance of clades with extinction-prone species and residual accumulation of clades with extinction-resistant species (Sepkoski 1984; Van Valen 1985).

4.1.4.2 Mass extinction

Superimposed on secular trends in background extinction are geological intervals in which vast numbers of species and higher taxa have disappeared, as illustrated in Figure 4.1-5. These intervals contain mass extinctions of the biota

Figure 4.1-5: Background and mass extinction for marine animal families through the Phanerozoic. Total extinction rates are given by the numbers of extinctions per million years over 76 time intervals. Points are separated into two classes; background extinction, within the dashed envelope, and mass extinction, represented by spikes above. The solid line is a linear regression fitted to the background points and exhibits a secular decline such that normal familial extinction in the Tertiary is about half the magnitude of that in the Cambrian. The spikes are the five major mass extinctions: ASHG = Ashgillian (end-Ordovician); GIV = Givetian, FRAS = Frasnian, FAME = Famennian (Late Devonian); GUAD = Guadalupian, DZHULF = Dzhulfian (end-Permian); NOR = Norian (end-Triassic); MAEST = Maastrichtian (end-Cretaceous). (Modified from Raup and Sepkoski 1982.)

– phenomena observed only in the fossil record but now being inferred to be impacting the living biota (e.g. Wilson 1992). There are problems, however, in comparing modern biotic crises to fossil events: many past mass extinctions are resolved only to coarse geological intervals, involving millions of years; most are measured at taxonomic levels above the species; and data come from habitats not necessarily relevant to present-day problems. The exception is the late Quaternary extinctions, discussed in 4.1.5.2.

The most severe mass extinction seen in the Phanerozoic fossil record of complex organisms is in the latest Permian (Palaeozoic–Mesozoic boundary), approximately 245 Ma ago (Figures 4.1-1 and 4.1-5). In the oceans, approximately 50% of animal families (Raup and Sepkoski 1982) and 80% of animal genera (Sepkoski 1989) disappeared. Raup (1979b) used similar figures in an exercise employing taxonomic rarefaction to calculate that 96% of marine animal species disappeared. The record for the terrestrial biota is less precise, but there is recent evidence of severe disruption among land plants (Retallack 1995). Data for terrestrial animals are even less secure, but Benton (1985, 1989) measured a 49% extinction of vertebrate tetrapod families and Labandeira and Sepkoski (1993) document a two-thirds extinction among insect families, as discussed in 4.1.3.4.

A major problem in the understanding of this most severe of Phanerozoic crises is that it is not known over what duration these massive extinctions occurred. Several decades ago, when geological knowledge was less detailed, it was assumed that the extinctions were spread over several tens of millions of years (e.g. Newell 1967; Hussner 1983). Recent explorations of the fossil record, especially in China, have narrowed the time span. Some marine data indicate that the end-Permian mass extinction was very abrupt, occurring over less than 10 000 years (Xu 1991) and catastrophic, leading to an unprecedented fungal bloom in the oceans (Visscher and Brugman 1988). However, Jin *et al.* (1994) and Stanley and Yang (1994) have argued that this was not a singular event but rather that there were two mass extinctions during the Late Permian, the first approximately 5 Ma before the Triassic, eliminating large numbers of foraminifera, brachiopods and echinoderms, and the second nearer to the Triassic, eliminating perhaps 80% of remaining species. Their hypothesis needs further scrutiny.

Despite the virtually unimaginable magnitude of the end-Permian events, the causes remain uncertain. Explanatory hypotheses have ranged from lowering of sea level (and reduction of habitat space; Newell 1967, T.J.M. Schopf 1974), to climatic change and reduction of endemism (Valentine 1971), widespread oceanic anoxia (Wignall and Hallam 1992), and supernova explosion (Schindewolf 1963). Erwin (1993) provides a detailed review of these hypotheses as well as geological evidence for environmental changes that were occurring near the end of the Permian. Of particular interest are major shifts in ratios of stable isotopes of carbon and oxygen in marine sediments (e.g. Baud *et al.* 1989), which suggest severe alterations of ecosystem functioning; the interpretation of causes, however, remains controversial.

Four other mass extinctions eliminated 15% or more of marine animal families (Figures 4.1-3 and 4.1-5) and there were perhaps another 15 lesser events of extinction (Sepkoski 1992a). The best-studied of the major mass extinctions is the most recent, at the end of the Cretaceous about 65 Ma ago. This event is best known for the extinction of dinosaurs and other Mesozoic 'reptilian' groups, such as the aerial pterosaurs and oceanic mosasaurs. Among marine invertebrates, ammonite cephalopods and reef-building rudistid bivalves became extinct, as did nearly all planktonic foraminifera.

Special attention has been directed to this event ever since L.W. Alvarez *et al.* (1980) proposed the controversial hypothesis that the extinctions were caused by the impact of a 10 km asteroid and the ensuing blanketing of the Earth by an opaque dust cloud that shut down primary productivity and caused herbivores, carnivores and suspension feeders to starve. This hypothesis was inferred from the discovery of positive iridium anomalies in a thin

clay layer at the Cretaceous–Tertiary ('K/T') boundary. Iridium is extremely rare in the Earth's crustal rocks as a result of geochemical differentiation, but is several orders of magnitude more concentrated in undifferentiated meteorites, especially chondrites (see W. Alvarez *et al.* 1982). Subsequent evidence for a major impact includes discovery of iridium anomalies in terrestrial as well as marine K/T layers (Orth *et al.* 1981); measurement of osmium isotope ratios characteristic of non-terrestrial small bodies; analyses of quartz grains in the clay layer, which show multiple shock lamellae characteristic of impact sites (Bohor *et al.* 1984); discovery of microspherules, interpreted as splash droplets of molten rock blasted from the impact sites (Montanari *et al.* 1983); and identification of K/T sandstone beds at various sites around the Gulf of Mexico and Caribbean that can be interpreted as tsunami deposits (e.g. Bourgeois *et al.* 1988). Finally, a subsurface, circular structure, 150–300 km in diameter, has been identified in Yucatán, Mexico, which can be interpreted as the K/T impact crater (Hildebrand *et al.* 1991; Sharpton *et al.* 1992).

This evidence is certainly not without controversy. A number of workers have interpreted the data as equally indicative of widespread explosive volcanism at K/T times (e.g. Officer and Drake 1983; Hallam 1987). Such volcanism could also have severely perturbed the biotic environment through climate change caused by the injection of sulphates and aerosols into the upper atmosphere. Glen (1994) provides a scholarly account of this highly charged issue.

The Alvarez hypothesis has been especially controversial among palaeontologists because fossils do not show the predicted catastrophic disappearance exactly at the K/T boundary. Some extirpated clades, such as the ammonites, display dwindling of biodiversity over tens of millions of years through the Late Cretaceous (e.g. Teichert 1986), whereas other groups perished more rapidly near the end of the Cretaceous but still exhibit graded extinction (e.g. Keller 1989). There have been three basic explanations for this empirical pattern. (1) The pattern is real, indicating that the K/T mass extinction must have been protracted over hundreds of thousands to millions of years, induced by accumulated climate change and not by catastrophic asteroid impact. Recoveries of Cretaceous species in earliest Tertiary sediments (e.g. N. MacLeod and Keller 1994) are used to reinforce this argument, as has the apparent selectivity of the extinctions (i.e. nearly whole-scale survival of some clades and complete disappearance of others). (2) The pattern is real but actually segregated into pulses of extinction ('stepwise extinction'; see Hut *et al.* 1987; Kauffman 1988). This hypothesis is bolstered by very good evidence that the widespread inoceramid bivalves and, perhaps, the reef-building rudistid bivalves became extinct approximately one half million years before

the end of the Cretaceous (Johnson and Kauffman 1990; K.G. MacLeod and Orr 1993). (3) The pattern is an artefact of fossil preservation and palaeontological collecting, so that the fossil patterns do not in fact contradict a catastrophic K/T event. Signor and Lipps (1982) demonstrated that incomplete preservation and sampling of the fossil record means that the last sampled specimen of a species will usually be older than the time of actual extinction. This will push observed extinctions downward from any catastrophic event horizon, making it appear gradual (or stepwise if sampling is uneven) if data are interpreted at face value. More recently, Springer (1990) used the techniques of Strauss and Sadler (1989) to test a case of putative gradual extinction toward the K/T boundary and found it lacking merit: the density of sampling was not sufficient to distinguish between protracted extinction in the latest Cretaceous and abrupt extinction at the K/T boundary (see 4.1.2.2).

These three points of view continue to be debated among palaeontologists, not only for the K/T mass extinction but also for the older events for which there are less perfect data: the end-Ordovician (439 Ma), Late Devonian (367 Ma) and end-Triassic (208 Ma). All of these are of approximately the same magnitude as the K/T event, but none has yielded strong evidence of extraterrestrial impact. The more numerous smaller extinction events of the Phanerozoic have attracted yet less scientific attention, and hypotheses offered for their causes are commensurately more poorly tested.

4.1.4.3 Recoveries from mass extinctions

Although few conclusions have yet been drawn about the causes of ancient mass extinction, one generalization can be made about the subsequent biotic response: global diversity in most settings recovers quickly on geological time scales (which, unfortunately, are long by human time spans). A possible exception to rapid recovery is marine reef communities (Cooper 1988; Kauffman and Fagerstrom 1993). Figure 4.1-1 shows that the five big mass extinctions of Phanerozoic marine animals were all followed by rapid rediversifications. After the end-Ordovician and Late Devonian events, marine diversity rebounded to previous levels of taxonomic richness; after the end-Triassic and end-Cretaceous events, marine taxonomic diversity rebounded to the general trend of increase established after the end-Permian. Interestingly, rates of rebound appear quite similar to rates of radiation early in the Phanerozoic. For example, the Silurian recovery from the end-Ordovician mass extinction occurred at about the same rate of diversification as the preceding Ordovician radiation of the Palaeozoic evolutionary fauna (Figure 4.1-1).

At finer scales of resolution, recoveries in the fossil record are more complicated. The best-documented

sequence of biotic events is that following the K/T boundary; the more poorly known sequences after older mass extinctions seem to be largely consistent in general pattern (Jablonski 1991; Sepkoski 1992a). The K/T recovery begins with nearly monospecific blooms of species. In the plankton this involves a surviving foraminifer from the epicontinental seas and continental margins, which has been interpreted as 'weedy' (D'Hondt and Keller 1991); in the benthos, it involves several surviving species of deposit-feeding bivalves that form very widespread, low-diversity communities in the earliest Tertiary of North America (Hansen *et al.* 1993). Both planktonic and benthic species then undergo 'boom-and-bust' cycles, with one or several 'opportunistic' species being very common for a short interval, only to be replaced by another widespread, low-diversity community (Kauffman and Erwin 1995). The cycles have durations of tens of thousands of years. Only after several such cycles does the evolutionary system settle down to more steady diversification and differentiation of biotic communities, often accompanied by the reappearance of 'Lazarus' taxa (Kauffman and Erwin 1995). Again, the time scales are short by geological standards but immense in relation to human experience.

4.1.5 Late Cenozoic biodiversity

The fossil diversity of the late Cenozoic, and especially of the Holocene (0–10 000 years), is the best-documented in all of life's history (see 4.1.2.2). The basic reasons for this are: (1) the taxonomy and phylogenetic relationships among species are best known by comparisons and phyletic connections to living organisms, which have far better known anatomy, behaviour, and geographic distributions; (2) the younger geological deposits holding fossils are not so eroded as the older fossil record, providing far greater sampling coverage of habitats and biogeographic provinces; and (3) there are many more means to date young fossils, ranging from short-lived radioisotopes (e.g. C-14, U-Th), to orbitally-induced Milankovitch cycles in stable isotopes and sediments, to much more precise biostratigraphies within ocean basins and on continental platforms. Thus, more has been determined about short-term biotic response to climate change, tectonic evolution and organic evolution.

4.1.5.1 Global diversity over the last 15 million years

There is accumulating evidence that global diversity today is lower than the levels attained 5 to 15 My ago. For the marine system, the most recent taxonomic data on animal families exhibit small reductions in the Pleistocene relative to the preceding Pliocene and Late Miocene (Sepkoski 1993; Benton 1995). Since higher taxa mute fluctuations in diversity of species and genera (Raup 1979b), the reductions at the latter levels were probably higher. These

reductions may reflect extinctions among temperate marine animals during the Pliocene and, perhaps, Middle Miocene. These extinctions are best documented for Pliocene bivalves and gastropods in the North Atlantic Ocean, North Sea and Mediterranean Sea, where indeed they may have been most severe (Stanley 1986; Vermeij 1989). These authors argue that the cause was probably decreasing temperature and increasing climatic gradient around the time of onset of northern glaciation, which particularly reduced habitable latitudinal ranges of north-temperate marine species. Since that incident there have been migrations of northern marine animals between the Pacific and Atlantic Oceans (see 4.1.5.3), but little rediversification of the fauna (Vermeij 1991a, b).

Among terrestrial animals, there also appears to have been a reduction in taxonomic diversity since the Miocene (Janis 1993). The best data are for large mammals of North America, where diversity seems to have been at a maximum about 15 Ma ago in the Middle Miocene (S.D. Webb 1989; Van Valkenburgh and Janis 1993; but see Stucky 1990). After that time, there were pulses of extinction in the early Late Miocene, end-Miocene and end-Pleistocene that reduced North American large mammal diversity from at least 120 species to 25 today (Van Valkenburgh and Janis 1993). This reduction occurred despite the arrival of various immigrant taxa from Asia and South America. It has been hypothesized that this reduction in biodiversity was caused by habitat change induced by general cooling: Miocene woodlands and open woodlands became largely replaced by savannah-like grasslands and eventually by steppe and desert habitats (Janis and Damuth 1990; S.D. Webb 1989; Janis 1993), with concomitant reduction in the diversity of mammalian woodland browsers. There was some diversification of smaller, more arid-adapted mammals (Van Valkenburgh and Janis 1993), but this was insufficient to reverse the general decline in mammalian diversity (S.D. Webb 1989).

4.1.5.2 End-Pleistocene extinctions

The most dramatic events in the reduction of late Cenozoic land animal diversity were the end-Pleistocene extinctions within and at the end of the last cycle of northern glaciation. In North America, where this event is best documented (Martin and Klein 1984a), the extinctions appear to be concentrated in the interval from 9000 to 18 000 years BP (Mead and Meltzer 1984). Some 43 genera of mammals became extinct, 91% of which were large (>5 kg; Barnosky 1989). This radically changed the faunal landscape from a biodiversity somewhat analogous to present-day Africa to the impoverished fauna of modern North America. Extinction struck the South American mammal fauna at approximately the same time (Marshall *et al.* 1982), eliminating 46 genera, mostly large (Barnosky 1989). In Eurasia, the extinctions may have been more protracted but

similarly eliminated most of the larger mammals (although dwarfed mammoths evidently survived on Arctic islands north of Siberia until 4000 years BP; Vartanyan *et al.* 1993). Extinctions struck Australia somewhat earlier, around 40 000 years BP (Martin and Klein 1984), and eliminated 21 mammalian genera, again mostly large (Barnosky 1989). Africa alone seems to have suffered only normal, background extinction, and it retains a comparatively diverse fauna of large mammals in savannah and forest habitats.

Despite the recency of this event, the cause(s) remain controversial. There are two hypotheses in contention: either human predation drove the animals to extinction (e.g. Martin 1984) or rapid climatic change at the end of the last glaciation caused the extinctions (e.g. Graham and Lundelius 1984). The human predation (or 'overkill') hypothesis finds support from (1) extinctions in Australia and the Americas, which are not contemporaneous but coincide with colonization by humans (see Martin and Klein 1984); and (2) archaeological sites, which demonstrate that the extinct large mammals were being hunted (e.g. Fisher 1984). In support of the climate change hypothesis, (1) earlier Cenozoic episodes of extinction were associated with climate change; (2) some animals that became extinct were actually rather small and unlikely to be affected by human predation (Graham 1986a, b); and (3) vast changes in the composition and structure of terrestrial communities were occurring with the retreat of glaciers at the end of the Pleistocene (see 4.1.5.3), which could have stressed animal populations. The problem with the last argument, however, is that similar community-level reorganizations must have occurred repeatedly during the past million years with the cyclic waxing and waning of glaciers, but no massive extinctions are evident; furthermore, similar community changes in the oceans at the end of the Pleistocene induced no extinctions (Vermeij 1991a, b). It is possible, however, that human predation was a co-factor with community-level stress during the last glacial retreat in inducing the extinctions, at least in the Americas.

4.1.5.3 Biotic invasions

Biotic invasions, or interminglings of species from different biogeographic provinces, has probably been occurring episodically throughout the Phanerozoic (Vermeij 1991b). However, with good sampling, dating and taxonomy, these can be documented most accurately over the last several million years in the fossil record. Perhaps the best known case of invasion is the 'Great American Interchange' of terrestrial mammals. Approximately 2.5 Ma ago, the Panamanian Isthmus formed, and land animals of South and North America began to disperse freely between the two continents (Marshall *et al.* 1982). The result was a huge change in the South American mammalian fauna, with extinction of many endemic species and addition of

many species of North American descent, but comparatively little change in the North American fauna.

Older overviews of this event argued that North American invaders actively displaced many southern mammals because of competitive superiority (e.g. Simpson 1950). More recent analyses have questioned this argument (e.g. Marshall *et al.* 1982; S.D. Webb 1991; Vrba 1992). Two patterns have been noted in the fossil record: (1) the documented number of genera that actually crossed the Panamanian landbridge is proportionally equal for each fauna, with the same percentage of South American mammals moving north as North American genera dispersing south (although the North American fauna was more diverse at the time) (however, S.D. Webb (1991), on the basis of cladistic arguments, suggests that a greater percentage of North American genera may have actually dispersed southward); and (2) the great accumulation of 'immigrant' taxa in South America was actually the result of radiation of new taxa of North American descent within that continent, whereas South American immigrants to the north did not diversify (Marshall *et al.* 1982). S.D. Webb (1991) and Vrba (1992) hypothesize that the radiation of North American descendants was permitted by prior extinction of South American endemics resulting from habitat change related to late Cenozoic cooling. The final extinction of many South American endemics appears related not to competition but to the end-Pleistocene extinctions which equally affected the descendants of North American immigrants (Marshall *et al.* 1982).

Invasions contemporaneous with the Great American Interchange have also been documented in the marine realm. Vermeij (1991a), in particular, has documented an impressive invasion of northern Pacific molluscan taxa into the Arctic Ocean and boreal to temperate regions of the North Atlantic Ocean following tectonic subsidence of the Bering Strait. Interestingly, this invasion followed (and did not coincide with) the Pliocene extinction of Atlantic temperate molluscs (see 4.1.5.1). Indeed, the northwestern Atlantic, which suffered the greatest extinction, received the largest proportion of invading species (Vermeij 1991a).

4.1.5.4 Holocene community disequilibrium

Biotic adjustments during the period from the Holocene to the end of the last glacial cycle were traditionally assumed to involve simple northward migration of intact communities as temperate and boreal latitudes warmed. Work over the last two decades on accurately dated tree pollen, beetle carcasses, small mammal bones, and marine foraminifera and molluscs has demonstrated this not to be true. The best-documented case is the response of trees in eastern North America over the last 18 000 years. Pollen records from long-standing lakes and bogs indicate that tree

species moved northward individually, rather than in highly integrated units (Davies 1986, 1989; T. Webb 1992). For example, the spruce–sedge association of the late glacial age broke up, and spruces are now associated with birches in modern forests (e.g. T. Webb 1992). Insect fossils illustrate similar changes in community structure and geographic distribution. Some beetles co-occurring in glacial lakes in Britain are now scattered across boreal Eurasia (Coope 1987, 1994). In North America, small mammals show similar patterns, although to a lesser degree (Graham 1986a, b, 1992). In the oceans, Buzas and Culver (1994) have demonstrated that communities of planktic foraminifera break up and reassemble with glacial–interglacial cycles, and Valentine and Jablonski (1993) have shown that Pleistocene molluscs shifted their geographic ranges individually throughout these climatic cycles, sometimes assembling into communities with no modern counterparts (see also Bennett 1990; Jackson 1994).

This widespread evidence, in the best-resolved part of the fossil record, of change in community composition with climate indicates that species respond to their own requirements for temperature, seasonality, nutrients and so on (e.g. Gleason 1926), more so than to the changing distributions and abundances of organisms with which they interact. In fact, the entire history of late Cenozoic marine and terrestrial animals, as presently understood, suggests a dominant role of environmental change in governing biodiversity. Only the longest-term changes seem to be controlled largely by evolutionary innovation and fundamental changes in community structure.

4.1.6 Conclusions

The fossil record provides rich data on biodiversity through the history of life. Geological occurrences of taxa, combined with geographical data, phylogenetic patterns, and anatomical, behavioural and ecological information for living organisms, can provide important information about how organisms have evolved, what kinds of adaptations have afforded success, and what kinds of environmental changes have promoted or subtracted from local and global biodiversity.

Evidence from the most recent parts of the fossil record will be best for understanding how biodiversity responds to changing environmental and biotic conditions. This part of the fossil record is best resolved in terms of time, geography and identity of organisms, and it records immense climatic changes during glacial–interglacial cycles and resultant habitat constriction and alteration. However, late Cenozoic changes still need to be placed within a broader evolutionary context in order to identify any possible unexpected biotic changes and to measure rates of biotic response and recovery, even at time spans longer than human scales.

4.2 Processes of genetic diversification

4.2.1 Introduction

Genetic differences among individuals within a species provide the foundation for the diversity among species and ultimately among ecosystems. In this chapter, we will describe the basic population genetic processes governing genetic diversity, focusing particularly on the role of genetic diversity in determining the ecological and evolutionary potential of species. As in most areas of biology today, our current knowledge of basic processes in population genetics is far from complete but progress is being made rapidly. Genetic diversity within a species is important for understanding biodiversity for two reasons. First, the potential for a species to respond to novel environments and to disturbances caused by human activities depends on the extent of diversity and the kind of diversity that is present. Second, current patterns of genetic diversity are the result of past events and can sometimes provide important clues to the history of a species and details of its current population structure.

We will begin by discussing different ways of describing genetic diversity, then we will review the basic mechanisms of genetic evolution, and finally describe what is known about how these mechanisms determine the extent of genetic diversity in natural populations. In each area, we will be able to touch on only the major points and not present many details. The reader will find more information in one of the standard texts on population genetics (e.g. Hartl and Clark 1989) or quantitative genetics (e.g. Falconer 1981). We emphasize in advance that there is no single definition of genetic diversity that can be used for all purposes, nor can we identify a single goal for the maintenance or management of genetic diversity. We will emphasize that genetic diversity, however defined, is not necessarily at an equilibrium even in species apparently undisturbed by humans. Fluctuations induced by climatic and ecological changes play an important and, for some species, a dominant role.

4.2.2 Measures of genetic diversity

Individuals of virtually all species are genetically unique. Even with clonal or asexual reproduction, mutation usually prevents perfect duplication of genomes. The question of interest is how to define genetic diversity in a way that will help us relate genetic processes to the ecological and evolutionary processes that govern biodiversity. There is a continuum of possible ways to describe genetic diversity but it will be convenient to consider diversity at the levels of single genetic loci, of quantitative characters and of the genome as a whole. A guide to the variety of techniques used to characterize genetic diversity is presented in Section 2.2.

4.2.2.1 Measures for single loci

In the light of modern molecular biology, it is no longer simple to define a genetic locus. Each nucleotide is

governed by Mendel's laws and for some purposes a detailed description of DNA sequences from different individuals is necessary to characterize variation in a region of the genome. For many purposes, however, a single locus can be defined in classical terms as possessing alleles that are inherited in a Mendelian manner and that can be recognized either because they produce visible differences among individuals (visible polymorphisms), or because they produce proteins that can be distinguished by electrophoresis or other biochemical methods (biochemical polymorphisms). In some cases, such as the Alcohol dehydrogenase locus in *Drosophila melanogaster* and the beta-haemoglobin locus in humans, alleles that have been defined by classical Mendelian analysis are distinguished by a single change in the amino acid sequence of a protein. In other cases, such as in several of the histocompatibility (HLA) loci in humans, alleles usually differ at several amino acid sites (Hartl and Clark 1989).

Mendel's laws were developed to describe inheritance in diploid species (those species, including humans and most higher plants and animals, that carry two copies of each chromosome) but they have been extended to haploid species (including bacteria) and polyploid species (many fungi, plants and a few animals). For simplicity, we will concentrate on diploid species in this chapter, but with the knowledge that the same principles apply with some minor modifications to other species.

When alleles can be distinguished, a complete description of a population at that locus is a list of the numbers of individuals with different genotypes. From the list of genotype numbers, the first step is to obtain genotype and then allele frequencies. For many purposes these lists themselves are of interest and often warrant careful examination before any summary statistics are computed. Unfortunately, readily available computer programs for the analysis of population genetic data sometimes discourage and even prevent a direct examination of the data themselves. This opportunity to compute summary statistics, without examining the genotype and allele frequencies they are based on, should be resisted by workers in the field.

From the genotype and allele frequencies, it is possible to compute one of several summary statistics that reflect different aspects of the patterns in allele frequencies. One summary statistic is the proportion of loci at which more than one allele is detected, that is, the proportion of polymorphic loci. Using electrophoretic methods, the proportion of polymorphic loci in animals is found to be between 10% and 40%, with vertebrates typically having lower values than invertebrates and outcrossing plants (Nevo 1978). Another statistic is the proportion of loci in an individual that are heterozygous, meaning that at these loci the individual carries two different alleles. Typical average values of the heterozygosity in animals fall

between 4% and 15% and the heterozygosity in a species tends to be positively correlated with the degree of polymorphism (Nevo 1978; see Section 3.1.3). Typically, vertebrates are less heterozygous than are invertebrates. In plants, heterozygosities vary from less than 1% in selfing herbs to 1–20% in herbs with a mixed mating system to 10–20% for outcrossing trees (Brown and Schoen 1992; see Section 3.1.3).

In quoting these or similar summary statistics or in using them to compare different species, it is important to keep in mind that they describe only the sample of loci used in a particular study, usually fewer than 100 loci out of the tens of thousands that are thought to be important to higher organisms. We do not yet know whether the loci that can be examined using electrophoretic methods, which tend to be soluble proteins that are relatively abundant in adult organisms, are representative of the rest of the genome, which contains many loci that are active for only short times during development. In fact there is usually found to be little correlation between these measures of genetic diversity and the genetic variance of quantitative characters, as discussed below, suggesting that loci that can be surveyed with electrophoretic methods are not typical of loci that underlie adaptive evolution.

For diploid species, another type of summary statistic tells us whether the data represent a population that is randomly mating. The Hardy–Weinberg formula relates the allele frequencies to the genotype frequencies in a randomly mating population – genotypes are in proportion $p^2:2pq:q^2$, where p and q are the allele frequencies. The ‘inbreeding coefficient’ measures the difference between the Hardy–Weinberg expectation and the observed genotypic frequencies. The inbreeding coefficient for an allele is positive if there are more homozygotes than expected and negative if there are fewer. For some purposes, it is convenient to compute a single statistic, often denoted by F or by F_{IS} , as an average inbreeding coefficient at a locus or as an inbreeding coefficient averaged across loci. The inbreeding coefficient does not describe the extent of genetic diversity but provides important information about the kind of diversity that is present. Non-random mating, including the interbreeding of close relatives, self-fertilization, and various forms of clonal reproduction, all act to create positive inbreeding coefficients. Some kinds of selection and migration act to reduce inbreeding coefficients and can make them negative. The average level of inbreeding in a species is intimately related to the potential for ‘inbreeding depression’ caused by some kinds of interactions among alleles, a topic discussed later (Wright 1931, 1978).

4.2.2.2 Multiple populations

When more than one population of a species is examined, measures of variation among populations as well as within

populations are needed. Many measures of genetic similarity or genetic distance have been proposed. They can be used either to quantify the differences between each pair of populations or to quantify the overall extent of genetic differentiation in a set of populations (see, for example, Nei 1987). Although many different measures have been proposed, they fall into two broad categories, depending on whether the extent of differentiation depends on the role of genetic drift or on the role of mutation. The measure of genetic distance proposed by Cavalli-Sforza and Edwards (1967) is in the first category and the one proposed by Nei (1972) is in the second category.

In considering the overall level of differentiation among populations, Wright’s F_{ST} is by far the most commonly used measure and is a natural extension of his coefficient of inbreeding within populations (Wright 1978). The S indicates that a subpopulation is being compared with the total population, denoted by T . For a locus with two alleles, the F_{ST} is the variance in allele frequency normalized by the average frequency. In a group of populations, the overall inbreeding coefficient F_{IT} (the individual I compared to the total) can be attributed either to differences in allele frequency among populations (F_{ST}) or to deviations from Hardy–Weinberg genotype frequencies within each population (F_{IS}). The value of F_{ST} is necessarily between 0 and 1, with 0 indicating the same allele frequencies in each population and 1 indicating fixed allelic differences between populations. There is a rich statistical theory, reviewed by Weir (1990), for estimating these parameters. Similar statistics can be defined for hierarchically structured populations, for example, populations grouped into neighbourhoods. Estimates of F_{ST} for natural populations vary widely, with some species (many birds, for example) exhibiting very little differentiation (low F_{ST} values) even over very large geographical areas, while other species (many salamander species) are highly differentiated (high F_{ST} values) even among nearby populations (Slatkin 1985).

All of the methods for describing variation at single loci can be applied directly to DNA sequence data, by treating each site as if it were a locus (Nei 1987). Levels of variation per nucleotide site found so far, primarily in *Drosophila*, are low, with the heterozygosities in the order of 0.1% and percentages of polymorphic sites in the order of 1%, although at the present time too few other species have been sampled to know whether these values are typical. Electrophoretically detectable variation in *Drosophila* species tends to be higher than in many other species so it would not be surprising if the same thing were true for variation at the DNA sequence level as well.

Levels of DNA sequence variation in mitochondrial DNA (mtDNA) have been studied extensively and been found to be much greater than for nuclear DNA in the same species because of the apparently higher mutation rate in

mtDNA. Most variation within species in mtDNA sequences makes no difference in amino acid sequence and hence makes no difference to the organism, but differences in sequence can be used to infer some features of the history of a species and as genetic markers that can distinguish subspecies and local populations. For that reason, they can be extremely useful in many applications (Avice 1993). There is no recombination in mtDNA in higher animals and there appears to be strictly maternal inheritance or nearly so, and hence the entire mitochondrial genome can be regarded as a single locus in a haploid organism.

4.2.2.3 Multiple loci

When two or more loci are considered together, one question of interest is whether the presence of an allele at one locus is, in a statistical sense, independent of the allelic or genotypic state of other loci. The most commonly used measure is the coefficient of 'linkage disequilibrium', defined as the difference between the frequency of a gamete and the frequency of that gamete under the assumption of independence (Weir 1990). Like the inbreeding coefficient, linkage disequilibrium is not itself a measure of the genetic diversity but an indication of the kind of diversity that is present, which in turn can provide important information about the principal forces affecting genetic diversity. For example, if high levels of linkage disequilibrium are found in a species, as is the case in some bacterial species, then in effect very few gametic types are present, suggesting that essentially independent clonally reproducing strains have been mixed in the same sample, while low levels of linkage disequilibrium imply frequent exchange among different strains (Maynard Smith *et al.* 1993).

4.2.2.4 Quantitative characters

A quantitative character is any measurable characteristic of the phenotype, but typically the term is used for characters that are affected by numerous loci of sufficiently small effect that it is either not useful or not possible to analyse them at the level of individual allele or genotype frequencies (Falconer 1981). A quantitative character may be a morphological character such as body or limb length, a physiological character such as respiration rate or metabolic efficiency, or a behavioural character such as running speed or learning ability. The classical methods of the analysis of variance were developed partly to analyse quantitative characters, and it is still useful to begin with a description in terms of phenotypic means, variances and co-variances of characters. Such studies of variation within a species form the basis for classical natural history and biogeography.

If breeding studies can be performed, it is possible to infer something about the genetic basis of quantitative characters, including genetic variances, co-variances and the extent of interactions between the genotype and the

phenotype. Although the application of these statistical methods is straightforward, it is still difficult to draw strong inferences about the relationship between variability at the genetic and phenotypic levels. There does not appear to be a correlation between levels of genetic variation in a species measured by the single gene measures described earlier and levels of genetic variance affecting quantitative characters (Hartl and Clark 1989). In some cases, characters exhibit roughly the same degree of variation in different species. For example, Yablakov (1974) found in a survey of mammals that skeletal characters typically had coefficients of variation of about 5% while physiological characters had coefficients of variation of about 15%.

An important measure of the genetic diversity affecting a quantitative character is the heritability (often denoted by h^2), which is the ratio of the additive genetic variance to the total phenotypic variance. Heritability provides a measure of the rate of response to selection on a quantitative character and thus provides an indication of the potential evolutionary response of a character to environmental changes (Falconer 1981). In a similar way, the additive genetic correlation between two characters provides a measure of the evolutionary interdependence of two characters, as discussed later.

4.2.2.5 Genomic variation

In some species there is abundant variation at the level of the entire genome. There may be variation in chromosome number, in the presence or absence of a wide variety of chromosomal rearrangements, in the presence or absence of auxiliary chromosomes and, in bacteria, the presence or absence of plasmids (White 1978). Differences in chromosome number or chromosomal rearrangements often lead to at least partial reproductive isolation (the inability to hybridize freely) and hence most of the variation of this type is found between rather than within populations. Variation in karyotype (the number and shape of chromosomes) is difficult to detect without careful analysis and is not necessarily associated with variation in obvious phenotypic differences. Differences leading to even partial reproductive isolation can be important for the management of populations, because of the consequences of inadvertently mixing karyotypes that lead to reproductive isolation in the same population (see Section 2.2.1).

4.2.3 Processes governing genetic evolution

We will describe separately the different processes that govern the evolution of allele frequencies and the distributions of quantitative characters, but it will be important to keep in mind the fact that all of these processes are acting at the same time. Their interactions are discussed in the next section, but it should be noted here that there are cases in which one or two of these processes dominate and the others can be ignored.

4.2.3.1 Mutation

A mutation is defined broadly as any change in a genome, from a change in a single nucleotide to a modification of the karyotype. The mutation process is still poorly understood, even though it is well established that some kinds of environmental stresses, such as X-rays, increase the mutation rate, possibly dramatically. There is general agreement that the kinds of mutations that occur (as opposed to the rate at which they occur) are independent of the environmental conditions experienced. The possibility of some directed mutations in bacteria is controversial, but even the proponents of that hypothesis say that there is no reason to extrapolate their results to eukaryotes, in which gamete formation is much more isolated from environmental influences (Lenski and Mittler 1993). In general, mutations do not arise to fill an environmentally imposed need. Mutation is ultimately the source of all genetic variation, but it is an unpredictable and so far uncontrollable source.

Changes, insertions and deletions of individual nucleotides occur at a very low rate which appears to be roughly the same in different parts of the genome and in different eukaryote species, approximately 4×10^{-9} per base pair per generation (Kimura 1983). This rate is very low but still high enough to ensure that, with genomes with sizes in the order of billions of base pairs, each individual carries several new mutants. Classical experiments in *Drosophila* genetics have estimated mutation rates to electrophoretically distinguishable alleles to be in the order of 10^{-5} per locus per generation at most (Hartl and Clark 1989).

These very low rates of mutation might suggest that mutation has very little effect on allele frequencies in each generation. Mutation provides new alleles, whose frequencies are then governed by other forces. For quantitative characters, however, mutation can be important for increasing the level of genetic variation. Several studies show that roughly 0.1% of the genetic variance of a quantitative character is introduced by mutation in each generation, presumably because those characters are affected by numerous loci each of which experiences mutations. In tens or hundreds of generations, it is possible for mutation to re-establish significant heritabilities in a species that has lost all variation because of an extreme reduction in population size (Hill and Caballero 1992).

There are some genetic loci that have relatively high mutation rates. As a result, these loci, often called VNTR (for 'variable numbers of tandem repeats'), are often quite variable and hence are quite sensitive indicators of population genetic processes (see also Section 2.2.1.2). VNTR loci have alleles that are distinguished by the numbers of repeated sequences of DNA. In some such loci, called microsatellites, the repeated motif contains only a few base pairs, while in others, called minisatellites, the

repeated motif contains 30 or more base pairs. Microsatellite loci are extremely abundant in the human and mouse genomes, which have been the most closely examined, and the genotypes are relatively easy to assess (Valdes *et al.* 1993). Heterozygosities at many VNTR loci are typically 70% or more. As a result they have become the mainstay of efforts to map the human and other genomes. Minisatellites have been used extensively in forensic studies attempting to define genetic fingerprints of individuals. Mutation rates at microsatellite loci are as high as 1/100 per generation (Weber and Wong 1993). The processes of mutation at VNTR loci seem to be different from those at other loci and to depend on errors in DNA replication caused by the presence of repeated sequences (Jeffreys *et al.* 1991). A vast majority of these loci apparently have no phenotypic effects, although a few microsatellite loci have been implicated in human genetic diseases (Kunkel 1993).

A quite different class of mutations occur because of the insertion of transposable elements, which are relatively small segments of DNA (in the order of a few thousand base pairs) that can insert themselves at most and possibly all places in the genome (Berg and Howe 1989). The insertion of a transposable element in a coding sequence can result in a drastic change in the gene product or the complete elimination of the product. Transposable elements have been found in all species that have been examined, including bacteria. Transposable elements transpose at apparently relatively low rates under most conditions (in the order of 10^{-5} per generation), but in two cases in *Drosophila melanogaster*, transposition rates are much higher under some conditions (the phenomenon of 'hybrid dysgenesis') (Engels 1983). Under those conditions, transposition results in measurably higher rates of accumulation of additive genetic variance of quantitative characters in addition to a rich abundance of deleterious, lethal mutants and chromosomal rearrangements. Such cases have not been found in other species but there seems in principle no reason why they could not occur. Mutations generated by such cases could become an important and powerful force for generating genetic diversity (Mackay 1985).

Rates of appearance of chromosomal rearrangements are low but occur frequently enough to be estimated reliably. Spontaneous mutation rates of chromosomal rearrangements, such as reciprocal translocations, centromeric fusions or inversions, are of the order of 10^{-4} to 10^{-3} per gamete and generation in taxa as different as grasshoppers, fruit flies, mice and humans (Lande 1979).

4.2.3.2 Genetic drift

Genetic drift is a process of change in allele frequencies caused by the unpredictable consequences of Mendelian inheritance. Even though alleles at a locus in a diploid

species appear in gametes with equal probability (which is equivalent to Mendel’s first law), a particular gamete contains one allele or the other. As a consequence, allele frequencies can change from generation to generation because only a sample of gametes will be represented in each generation. Population size is the most important determinant of genetic drift, with small populations being much more strongly affected than large ones. There is currently great concern about the small sizes of many natural populations. Small size leads to higher risk of extinction through demographic effects and also poses genetic problems. Heritabilities can be reduced because of the loss of alleles and the genetic correlations among characters can be altered because only a few pleiotropic alleles, alleles that affect two or more phenotypic characters, might remain. Both effects would tend to restrict the response to new environmental conditions which might well accompany a reduction in population size. Furthermore, small population sizes may lead to increased homozygosity and consequently inbreeding depression.

Genetic drift depends on a variety of factors, whose net effect can be summarized by a single quantity, the ‘effective population size’ (Wright 1938). The effective size is generally less than the total number of individuals present, the ‘census size’. The effective size depends on the breeding system, the age structure, the sex-ratio and other factors. For most species, only a fraction of the individuals present are actually involved in reproduction; individuals may be sexually immature, unable to compete for mates or simply be unlucky and not find a mate. Individuals that do find a mate may leave no offspring anyway because of high juvenile mortality. The effective population size, N_e , corresponds to the size of an ideal randomly mating population which would offer the same opportunity for genetic drift as the real population.

The effective population size may in fact be much less than the census size. For example, in a population that is changing in size from generation to generation, the effective size is the harmonic mean of the population sizes, that is $1/N_e$ is the average of $1/N$. In general, the harmonic mean depends most strongly on the smaller population sizes. If there are N_m males and N_f females in the population, the effective population size will be equal to $4N_mN_f/(N_m + N_f)$. For example, a population consisting of one male and 100 females will have an effective size of roughly 4. In an age-structured population, in which individuals of different ages are present at the same time, the effective size depends in a complex way on the birth and death rates for each age class, but the effective size is always smaller than the census size (Hill 1972). For humans, for example, the effective size is approximately one-third of the census size (Charlesworth 1980). If there is extensive clonal reproduction as well as overlapping

generations, the effective size can be quite small. Orive (1993) has shown that the effective sizes of two species of corals are only about 3% of the census size.

In general, genetic drift reduces genetic diversity in a population at a rate determined by the effective population size. If H is the proportion of heterozygous loci in a randomly mating population, then H is reduced by a factor of $[1 - 1/(2N_e)]$ each generation by genetic drift (Crow and Kimura 1970). The additive component of the genetic variance of a quantitative character is reduced by the same fraction. Even when N_e is relatively large, there can be a substantial reduction in heterozygosity on a time scale of N_e generations (Figure 4.2-1). In a population reduced to a very small number of individuals, heterozygosity can be lost almost completely, as has apparently happened with cheetahs (*Acinonyx jubatus*), in which only 2 of 49 loci were found to be polymorphic, many of which are polymorphic in other mammals (O’Brien *et al.* 1983; but see May 1995). The ‘founder effect’, in which genetic variability is greatly reduced when a population is founded by a small number of individuals, is an example of genetic drift that may play an important role in the formation of species.

4.2.3.3 Natural and artificial selection

The diversification of species and their adaptation to environmental conditions are governed largely by natural selection, as first described by Darwin. Darwin’s theory of natural selection was integrated with the Mendelian theory of inheritance in the early 1900s, leading to the neodarwinian or synthetic theory of evolution in which selection within species still plays the dominant role (Huxley 1942). More recently, Gould, Eldredge and other proponents of the punctuated equilibrium theory of evolution have emphasized that the synthetic theory alone does not account for general patterns observed in the fossil record or for large-scale patterns in species diversity, and that selection among species must also be considered (Stanley 1979).

Figure 4.2-1: Loss of heterozygosity by genetic drift in two populations having effective population sizes of 50 and 500, respectively. Heterozygosity has been set at 100% in the starting generation.

Selection within a population occurs whenever inherited characteristics of individuals affect an individual's ability to survive and reproduce. We can distinguish natural selection, which is caused by naturally occurring environmental conditions affecting survival and reproduction (Darwin's 'struggle for existence'), from artificial selection, which is imposed by humans for altering and improving domesticated species. The same principles apply to both but there are several important differences between them. First, natural selection is typically relatively weak, with only small differences between individuals affecting their survival and reproduction, while artificial selection is almost always quite strong, with only a few of a large number of individuals being chosen as parents of the succeeding generation. There can be very strong episodes of natural selection caused by rapid changes in environmental conditions, including changes caused by humans, but that is not thought to be typical of most characters in most species (Endler 1986). Second, natural selection acts for the entire lifetimes of species, possibly millions of years, while artificial selection acts over a few and at most tens of generations. Finally, the way in which artificial selection is performed can be adjusted to ensure that continued progress will be made, because there is a definite goal and because progress can be monitored. In contrast, there is no goal under natural selection and environmental conditions may change in such a way that a population or species will go extinct, at least in one geographical area and possibly over the entire species range, rather than evolve in response. We will discuss later the importance of these differences.

4.2.3.3.1 Selection on phenotypic characters. Selection depends on differences among individuals in phenotypic characters, and depends on the genotypes only as far as phenotypic differences can be traced to differences in genotype. It is often useful to speak of a phenotype – a particular character or combination of characters – as conferring 'fitness' on an individual and then to predict the effects of selection under different conditions by computing differences in fitness among individuals. In using this terminology, we make some important assumptions that are often not stated explicitly. In saying that an individual with, for example, a body length of 6 cm is twice as fit as an individual with a body length of 8 cm, we are saying that, all else being equal, individuals of length 6 cm will have twice as many offspring as individuals of length 8 cm. The phrase, 'all else being equal', means in this case that we imagine a very large number of individuals in which their genomes are made up of random combinations of genes but subject to the constraint that they all are 6 cm long.

Selection can result in a change in the genetic and phenotypic composition of a species but it can also result in a change in numbers, sometimes a dramatic change that

results in a different ecological role. For example, a pest species without insecticide resistance may be rare and found only in microhabitats that provide refuges from the insecticide. But once resistance evolves, that pest could occupy a much larger range and have a significant effect on many other species. The history of pesticide application shows many examples of this phenomenon.

Consider a single character of measure x . There is 'directional selection' if individuals with larger (or smaller) values of x have higher fitness. If $w(x)$ is the relative fitness of an individual with phenotype x , then there is directional selection if $w(x)$ is an increasing (or decreasing) function of x (Figure 4.2-2). Virtually all artificial selection is based on performing directional selection on one or more characters. There is abundant evidence for directional selection occurring in natural populations as well (Endler 1986). An alternative to directional selection is 'stabilizing selection' in which extreme values of a character have a lower fitness and an intermediate value, the optimum value, has the highest fitness. Stabilizing selection is performed on domesticated species to maintain the ideal types of varieties or species. There is some evidence for stabilizing selection in natural populations as well, but at present it is not possible to know the relative importance of stabilizing and directional selection in nature. 'Disruptive selection', in which extreme values of the character have the highest fitness, is also found in nature but is thought to be less common. Disruptive selection is probably not practised intentionally on a single population of a domesticated species because directional selection in different directions on isolated populations would be much more effective.

4.2.3.3.2 Selection on individual loci. The relationship between selection practised on phenotypic characters and selection that is affecting allele and genotype frequencies is far from clear. Much of the existing theory depends on assumptions that cannot currently be tested in most cases but that are at least consistent with what is known about development and with extensive experimental studies in quantitative genetics. Nevertheless, we are aware that as more is understood about development, existing theory will have to be augmented or replaced by more realistic theory.

If each allele carries with it a 'dosage' that it contributes to a quantitative character, as illustrated in Figure 4.2-3, then the relative fitnesses of genotypes at a locus can easily be related to selection on the character. Directional selection on a character always favours one genotype and thus always acts to fix one allele and thus eliminate genetic variation at a locus. Intuition might suggest that stabilizing selection would tend to preserve variability at each locus affecting a character but that is not true in general. It is true that intermediate genotypes will have intermediate values of the character but well-established theory shows that in almost all cases stabilizing selection will result in the

Figure 4.2-2: Fitness of individual phenotypes under (a) directional selection, (b) stabilizing selection, and (c) disruptive selection.

optimal phenotype being achieved by fixing different combinations of alleles at different loci rather than by preserving variability at each. It is also true, however, that stabilizing selection is much less efficient than directional selection in eliminating genetic variability (Lewontin 1964). Disruptive selection in natural populations results in the maintenance of genetic variation but usually at only one or two loci which ‘switch’ the phenotype from one extreme phenotype to another (Ford 1964).

It is also possible that genotypes of diploids are not neatly ordered in their effects on a character, as illustrated in Figure 4.2-3, a situation described as ‘overdominance’ of the alleles. In such cases, both directional selection and stabilizing selection can maintain genetic variation. One example of overdominance maintaining genetic variability is that of the allele of beta-haemoglobin causing sickle-cell anaemia in some human groups in malarial regions in Africa. Individuals heterozygous for this allele are more resistant to malaria, so that the allele is maintained in relatively high frequency despite having very severe effects on individuals homozygous for the allele. It is not currently known how common this situation is, and there are very few other examples in which it can be demonstrated that selection alone is maintaining variation at a locus or set of loci. It is currently controversial as to whether overdominance is present at most or even many loci and hence whether selection alone generally acts to maintain or

eliminate genetic diversity. It is important to note that if overdominance is maintaining genetic diversity at a locus, allele frequencies will tend to be relatively high. For example, alleles causing sickle-cell anaemia are found at frequencies of 10% or more (Cavalli-Sforza and Bodmer 1971).

4.2.3.3.3 Spatial and temporal variation in selection. Spatial and temporal variation in conditions experienced by a population also affects selection. The effects of such variation depend on the scale of variation relative to the organism. Variation over very large distances can result in geographical clines in one or more phenotypic characters, something observed in many species that have large geographical ranges (Endler 1977). Changes that occur slowly can result in long-term trends that can be reversed if conditions change. Variation over smaller geographical scales can result in what is equivalent to disruptive selection, with some phenotypes being favoured in some parts of the range and others favoured in other parts. Directional selection may change direction, resulting in what is effectively stabilizing selection, a phenomenon that

Figure 4.2-3: Contribution of one locus to a quantitative character. The genotypic values of three genotypes, A₁A₁, A₁A₂ and A₂A₂ are compared under conditions of (a) co-dominance, (b) dominance of A₂, and (c) overdominance.

has been demonstrated in some bird species. At the level of individual loci, spatial and temporal variation in selection usually result in the maintenance of more genetic variation than would be found in the absence of such fluctuations, and some authors, Gillespie (1991) in particular, have argued that fluctuations in selection play a dominant role in the maintenance of genetic variability.

4.2.3.3.4 Selection on multiple characters. Considering each character in isolation is a reasonable starting point but in reality an individual's survival and reproduction depend on several characters. In natural populations, it is currently impossible to know whether only a few characters strongly influence relative fitness or whether a large number of characters are important simultaneously. It is clear that combinations of characters are selected together because of their functional integration. For example, natural selection favours high running speed in many animals, either to make them more efficient predators or to make them more likely to escape predators. A wide variety of morphological and physiological characters contribute to running speed, including, in vertebrates, limb dimensions, the detailed structure of various muscles, and features of the respiratory and circulatory systems.

This example illustrates a common problem in discussing the evolution of quantitative characters: namely, what is a character? We can treat running speed as a single character, as has been done for centuries by breeders of racing animals, or we could treat all characters affecting running speed separately. At the genetic level this distinction is more apparent than real. With both ways of looking at the problem, the same loci will be involved in the response to selection on running speed and ultimately it is the variation at the genetic level that determines the potential response of running speed to selection. Selection on several characters at once will reduce genetic diversity in general unless there is extensive overdominance of the loci affecting those characters.

4.2.3.3.5 Response to selection. For a single quantitative character, the short-term response (R) to selection can be predicted from the heritability (h^2) of a character and the selection differential (S), which is the difference between the mean of the character in the selected parents and that of all potential parents: $R = h^2S$, which is called the 'breeders' equation'. This theory provides adequate if not perfect predictions over five to ten generations (Falconer 1981). On this very short time-scale, heritabilities do not tend to change by much. Over a longer time-scale, tens to hundreds of generations, the simple theory is no longer adequate especially when very strong directional selection is applied. The average value of a character often stops at a 'plateau' after which further response to selection does not occur. The location of this plateau differs from character to character and also depends on the strength of selection applied. Generally, weaker selection results in longer continued

response and ultimately a greater response, suggesting that mutations occurring during the selection experiment are permitting further response (Hill and Caballero 1992).

One important generalization can be made in spite of the lack of ability to predict the long-term response to artificial selection. In domesticated species and those studied in laboratories, virtually all characters that have been subject to directional selection respond sufficiently that their mean values lie outside the initial range of variation. The mean value of a character can almost always be changed by five or ten times the initial standard deviation (Falconer 1981), which implies that abundant variation is present at loci affecting virtually all quantitative characters. As a consequence there is the potential for rapid genetic response of natural populations to most kinds of selection. This generalization does not, however, imply that rapid evolution will occur in natural populations in response to all environmental changes. As we have emphasized, natural selection cannot generally target a particular character. A drastic change in environmental conditions may result in a demographic rather than an evolutionary response. A species could change the part of the habitat it uses by choosing microhabitats to which it is already adapted; it could change its geographical range, or it could simply go extinct. Polar bears, musk oxen and representatives of other classes of mammals have evolved adaptations to Arctic conditions, but there are no examples of similarly adapted perissodactyls (horses and their relatives) or of primates (other than humans). Which types of species can evolve adaptations in a particular situation is unpredictable and depends on both genetic and ecological factors that differ among species. Furthermore, the fact that a suite of adaptive characters has evolved once, does not mean that it will necessarily evolve a second time in a different lineage. Penguins evolved in the Antarctic but no birds have evolved a similar set of characteristics in the Arctic. Cacti evolved in New World deserts but not in the Old World. The success of introduced *Opuntia* in deserts throughout the world shows that their adaptations would be useful in the Old World deserts had they evolved there.

When two or more characters are considered together, the response to selection becomes more complicated. A genetic correlation between two characters implies that they are affected to some extent by the same pleiotropic loci. As a consequence, selection on one of the characters results in a response of the other. It is often useful to distinguish between the direct response of selection, which is the response to selection affecting that character, from the indirect or correlated response of other characters affected by pleiotropic loci. The correlated response to selection can provide a powerful constraint on evolution. It is often found, for example, that fertility and other characters directly affecting reproductive success decrease when strong selection is applied to other characters. In

some cases, the response to artificial selection is limited by the fertility of the selected lines (Falconer 1981). The correlated response can play a role in determining how a species will respond to environmental change. As Stebbins (1950) has emphasized, evolution seems to follow a 'path of least resistance', which means that the genetic changes that occur under different conditions will be those that are the easiest to achieve. The patterns of genetic correlations among characters are the main determinants of paths of least resistance. Unfortunately, genetic correlations among characters are difficult to estimate even for domesticated species and they can change in response to selection. Hence, it is nearly impossible to predict the path of least evolutionary resistance for a species subject to new conditions. The best guide is probably the response of similar species to similar changes.

4.2.3.4 Dispersal and gene flow

Species often occupy large geographic ranges, which creates the opportunity for genetic and phenotypic diversity within as well as between species. According to the theory of 'allopatric speciation' (Mayr 1963), geographic variation within a species provides the raw material for the formation of different species. Furthermore, patterns of geographic variation can provide important clues to the working of other population genetic processes. The movement of individuals from one location to another, the process of dispersal or gene flow, tends to homogenize populations and eliminate local differences.

The extent of gene flow can be radically altered by humans. It has for long been a common practice in forestry and fisheries deliberately to release organisms into areas inhabited by conspecific populations, and inadvertent releases caused by the recent world-wide acceleration in human transportation by road, air and sea may dramatically alter the frequency and distances over which long-distance dispersal occurs in other organisms (see Section 11). For example, many coastal marine taxa are now spreading world-wide in the ballast water of ships (Carlton and Geller 1993). Another example is the rapid spread of the amplified esterase B2 alleles which confer insecticide resistance to *Culex pipiens* (Raymond *et al.* 1991).

Gene flow can occur because of the movement of individuals between established populations or because of the establishment of entire populations. Some species, including most weeds and many parasitic species, have a structure that can be best described as a metapopulation (a population of populations – see Sections 4.3.1 and 4.4.2), in which each population is transient, but in which a collection of populations persists through continued extinctions and recolonizations (Olivieri *et al.* 1990). Under some circumstances, the recolonization process can be the dominant cause of gene flow (Wade and McCauley 1988; Gilpin 1991). Extinctions and recolonizations also effect

the heterozygosity of metapopulations. Without extinction, a subdivided population with little gene flow among subpopulations loses genetic variation at a slower rate than a panmictic population of the same total size, because different alleles tend to be fixed in different subpopulations. With extinctions and recolonizations, however, the metapopulation may lose genetic variation at an unexpectedly high rate (Gilpin 1991).

4.2.3.5 Recombination

Genetic loci are arranged on one or more chromosomes and hence sets of alleles tend to be inherited together. Recombination in eukaryotic organisms and various other methods for exchanging genetic material in prokaryotes (transformation, for example) rearrange alleles among chromosomes. Recombination does not itself create genetic diversity at each locus but it can create new combinations of alleles at different loci by mixing alleles from different individuals. Without recombination of any type each individual is genetically independent of all others and behaves effectively as a separate species.

Species differ enormously in the extent to which their genomes are affected by recombination. The mode of reproduction and the breeding system largely determine the opportunities for recombination. Outcrossing, as opposed to self-fertilization, makes recombination more important. Most higher animals (including all mammals and birds) cannot self-fertilize; nor can many plants: but many plants and some lower animals can. Self-fertilization is common in plants, and in some animal groups such as snails. It does not prevent recombination, but highly self-fertilizing species tend to be very homozygous and in that case recombination has little effect. There is no recombination when organisms reproduce asexually, either by direct budding of individuals or by the production of young from unfertilized eggs. Many species, such as aphids, have the capacity for long periods of asexual reproduction, punctuated by occasional episodes of sexual reproduction, thus ensuring that some genetic exchange among individuals will take place. Prokaryotes do not have sexual modes of reproduction but have a variety of methods for exchanging genetic material between individuals. There appear to be substantial differences among bacterial species in the extent of genetic exchange. For example, *E. coli* seems to be essentially clonal while *Salmonella* appears to be essentially randomly mating (Maynard Smith *et al.* 1993).

4.2.4 Maintenance of genetic diversity

As we have discussed, there is abundant genetic variability at all levels, from nucleotides to quantitative characters, in most species that have been studied. It is currently not known how the various population genetic forces together determine levels of genetic variation. This problem is of interest in its own right, but it is also of great importance

for our understanding of the relationship between genetic and species diversity, and between genetic diversity and the persistence of natural populations. The potential for adaptive responses to changes in environmental conditions depends on the genetic diversity present and how that diversity is maintained. Here, we will try to summarize what is known and make clear what remains to be learned.

Obviously mutation creates variability and genetic drift tends to remove it. For many parts of the genome, it appears that these two forces are sufficient to account for both standing levels of variation and rates of evolution. That is particularly true for the non-coding DNA, intron sequences, and silent DNA variations (i.e. those that do not change a codon and hence do not change the protein coded for). These observations, which form part of the foundation of the 'neutral theory' of molecular evolution (Kimura 1983), do not help us understand the maintenance of genetic variation that is the basis for adaptive evolution.

4.2.4.1 Mutation and selection

Selection that tends to decrease diversity will be opposed by mutation that tends to restore it. For individual loci, theoretical predictions are clear and simple. If μ is the mutation rate to an allele that reduces fitness by an amount s (i.e. the fitness is $1-s$ relative to an individual without the allele), then the equilibrium frequency of the deleterious allele will be approximately $(\mu/s)^{1/2}$ if the allele is recessive and approximately μ/s otherwise (Hartl and Clark 1989). The difference between alleles that are recessive and those that are not seems minor, but in fact for realistic parameter values there is a qualitative difference between the two cases. For example, if $\mu = 10^{-5}$ and $s = 0.9$, indicating that the allele causes a severe genetic condition, the equilibrium frequency if the allele is recessive is about 3/1000 and about 1/10 000 if it is not recessive. Thus selection is much less effective in removing recessive deleterious alleles than it is in removing those that are not recessive. This simple result explains why individuals of many species carry recessive deleterious alleles, a fact that has important consequences for inbreeding depression and outbreeding depression, discussed below.

The theory describing the balance between mutation and selection for quantitative characters is more difficult to understand and its empirical basis is much more controversial. Turelli and Barton (1989) review the literature in this area. There is extensive genetic variation for almost all quantitative characters and it is generally agreed that selection of some kind is important for many quantitative characters, but there are still important unanswered questions about what role selection plays. In particular, we do not know whether most variation in quantitative characters is attributable to a few loci, each of which has a significant effect, or to a large number of loci each of which has a smaller effect. In the first case, each

locus would be relatively strongly affected by selection on the character and in the second case each locus would be affected only slightly. At present, breeding studies suggest that quantitative characters are affected by several loci (four or more) but the methods do not have the resolving power to distinguish with confidence between five loci and 100, because too many untestable assumptions are needed to make such estimates (Lande 1981). New methods for finding loci with strong effects on quantitative characters (e.g. Lander and Botstein 1989) hold great promise to resolve this problem but at present their power depends on having a very detailed linkage map which is unavailable for most species.

It is clear that the short-term response to selection of most kinds is possible and not limited by lack of genetic variation of the right type. It does not appear to be necessary to wait for a mutation of the right type to occur before most species can respond to most types of selection. Over longer time-scales we know much less, and it may well be that certain kinds of change under selection do not occur because of the lack of mutations. We can illustrate the problem by considering the loss of bilateral symmetry. In laboratory studies of insects and vertebrates, mutations that produce a consistent difference between the right and left sides seem to be very rare. In *Drosophila*, for example, it was impossible to select for consistent difference in wing size (Maynard Smith 1956). (This is one of the rare cases in which response to strong artificial selection on a character – the difference in wing size on the right and left sides – was not obtained). It is clear, however, that bilateral symmetry has been lost in some fishes, such as sole. Presumably mutations breaking down bilateral symmetry were favoured in the ancestors of such species because asymmetric individuals were favoured by natural selection. There are no species of mammals with a comparable extent of asymmetry.

We do not know whether no such strongly asymmetric mammals have evolved because sufficient mutations of the right type have not occurred, or whether natural selection has never favoured such mutations because highly asymmetric mammals were always at a disadvantage. In the former case, we would say that evolution was limited by the lack of mutation, or that evolution was limited by a 'developmental' constraint. That is, the system of mammalian development does not permit the expression of mutants that drastically modify bilateral symmetry. If, on the other hand, such mutations can readily occur but, for unknown reasons, bilateral symmetry in mammals has always been favoured by natural selection, then evolution is not limited by mutation or by developmental constraints. At present, there is considerable controversy over the relative importance of developmental constraints and selection, especially in large-scale evolutionary transitions. Developmental constraints could also play an important

role in the capacity of a species to adapt to novel environmental conditions. Even if suitable mutations would ultimately occur and permit the response to selection created by new conditions, a species could go extinct before such mutations could occur.

4.2.4.2 Inbreeding depression and heterosis

When closely related individuals interbreed, their offspring are often less fit, and sometimes much less fit, than either of the parents. This is the phenomenon of inbreeding depression. Heterosis is the opposite: offspring of unrelated parents tend to be more fit than those of related parents. Both heterosis and inbreeding depression are explained by the same two genetic mechanisms: the presence of deleterious recessive alleles and of alleles that are overdominant (i.e. with higher heterozygote fitness). For both kinds of alleles, the increased homozygosity of inbred individuals would be expressed as lower fitness. Similarly, outbred individuals would tend to be heterozygous at more loci and hence exhibit heterosis. The relative importance of recessive and overdominant alleles in accounting for inbreeding depression is currently unknown and is very controversial. Many genetic studies show that individuals carry numerous recessive deleterious alleles while examples of overdominance are rare. Nevertheless, a few strongly selected overdominant alleles could far outweigh the effects of recessive alleles because each recessive deleterious allele would be expected to be in low frequency while overdominant alleles would tend to be maintained in relatively high frequency.

Inbreeding depression is potentially important for natural populations that have been substantially reduced in size, as is the case for many endangered species. If the average fitness is lowered because many individuals become inbred, the resulting inbreeding depression could further lower the reproductive capacity of the species and further reduce the population size, a phenomenon that has been described as 'genetic meltdown' (Lynch *et al.* 1993). Whether inbreeding depression is a potential problem for a species depends on its history and breeding system. Many species are commonly inbred because populations are typically founded by one or a few individuals – many parasitic populations are founded by a single fertilized female, implying that the next generation is produced exclusively by brother–sister matings – or because individuals are self-fertilizing. In such species, there may be little potential for inbreeding depression because individuals are already homozygous and deleterious recessive alleles would have been largely eliminated by selection (Shields 1982).

4.2.4.3 Selection opposed by gene flow

The study of geographic variation has a central position in evolutionary biology because differences among different

populations of a species often provide important clues to processes affecting those populations. Geographic differences among populations can result from genetic drift alone, as discussed above, but in many cases the level of variation in one or a few characteristics is much greater than for other characteristics, suggesting that local differences in selection are responsible. In fact, geographic variation in selection has been demonstrated in many studies of natural selection (Endler 1986).

Geographic differences caused by selection are particularly important for understanding biodiversity. Different populations of the same species may be adapted to rather different local conditions. In some cases, those differences are evident to humans: for example, populations of many species have colours or patterns adapted to substrates they typically occupy. In the classic studies of industrial melanism, for example, moths of several species have been shown to be adapted to trees that either are or are not blackened by soot from factories (Ford 1964). The agent of selection, predation by birds, has been shown to be sufficiently powerful to lead to the adaptation of moths to local conditions in a matter of tens of generations.

The selection leading to industrial melanism was obvious to human observers because we have roughly the same visual capacities as the predatory birds involved. In other cases, that is not necessarily true. There are local differences in the mineral content of soils but it is usually impossible to predict whether those differences lead to local adaptations or not. Numerous studies of the evolution of tolerance of plants to heavy metals in soils near mines (Ford 1964) show us that adaptation to local conditions can occur quickly in plants but it is not yet clear whether such examples are typical or just the consequence of the extremely strong selection created by human activities.

Selection pressures may vary on very different geographical scales, from global to local. Consider climate as an example. Differences in climate can cause large-scale differences in selection, such as those leading to the general trend towards larger body size of many organisms from the Equator to higher latitudes, a trend known as Bergmann's rule (Mayr 1963). On a much smaller scale, microclimatic differences between exposed and shaded localities may lead to genetic differences between local populations of organisms with limited dispersal capabilities. Thus, climatic selection can vary geographically in a large-scale, clinal fashion as well as in a small-scale, mosaic one. Both of these patterns may affect the same morphological trait, such as shell colouration of the snail *Cepaea* (Ford 1964). Physiological and behavioural traits can also respond to geographic variation, although much less is currently known about that area (Garland and Adolph 1991).

The potential for the establishment of local differences depends on the balance achieved between gene flow and selection. The theory for the balance between selection and

gene flow shows that there is a ‘critical length scale’ (l_c) below which selection cannot overcome gene flow. For a single locus with selection of intensity s against one genotype, $l_c = l/(s)^{1/2}$, and for a quantitative character in which the strength of stabilizing selection is w , $l_c = l/(w)^{1/2}$ (Slatkin 1985), where l is roughly the average distance between the place of birth of an individual and where it mates. If selection varies on a scale less than l_c , the allele or phenotype frequencies will not respond and the population will be unable to adapt to those conditions, while adaptation will be possible to variation on a geographical scale greater than l_c , as illustrated in Figure 4.2-4.

Hybrid zones between species or subspecies present a somewhat different situation because individuals on the two sides of the zone often differ in numerous characters and because there is generally selection acting against hybrid individuals. The theory of hybrid zones shows that such conditions often lead to very steep gradients in several characters in the same location even if that location does not correspond to the location of change in the selective conditions (Barton and Hewitt 1989). In effect, selection against hybrid individuals, which can often be strong, overwhelms selection from environmental factors. An important consequence of this theory is that, although geographical variation in selection can lead to substantial differences between nearby populations, it is not necessary that observed differences between populations imply strong selection.

Figure 4.2-4: Frequency of a selectively favoured allele in an environmental pocket (hatched area) which is (a) shorter than the critical length, or (b) longer than the critical length. Position is measured relative to the critical length, l_c .

4.2.4.4 Outbreeding depression

One of the consequences of geographical variation in adaptive characters is that immigrants to an area may not be adapted to the local conditions. When a reduction in fitness follows the interbreeding of distantly related parents, it is usually referred to as ‘outbreeding depression’, regardless of the mechanism causing the fitness loss. Templeton (1986) emphasizes that outbreeding depression can also result from the adaptation of alleles to other alleles that may be missing from other populations. This process of ‘genomic coadaptation’ could produce outbreeding depression even in the absence of geographic variation in selection.

Outbreeding depression has been quantified in several plant species. In *Ipomopsis aggregata*, the offspring fitness of crosses between plants 100 m apart was significantly less than the offspring fitness of 10m outcrossers (Waser and Price 1989). Interestingly, this study indicated an optimal outcrossing distance, as inbreeding depression was found in crosses between plants 1 m apart. Our knowledge of outbreeding depression in animals is more tentative, partly because of the difficulty of doing transplantation experiments with natural populations of animals, and partly because of the need to follow the study animals for more than one offspring generation. One widely known case indicates that outbreeding depression can have dramatic consequences for the viability of animal populations. When Tatra Mountain ibex (*Capra ibex ibex*) in Czechoslovakia became extinct through overhunting, ibex were successfully transplanted from nearby Austria (Templeton 1986). But later additions to the Tatra herd of bezoars (*C. ibex aegagrus*) from Turkey and of Nubian ibex (*C. ibex nubiana*) from Sinai, resulted in hybrids which gave birth to young during the middle of the winter when no young could survive, and the population went extinct.

4.2.4.5 Gene flow opposed by genetic drift

Geographic variation in neutral alleles does not lead to adaptive differences but neutral alleles can serve as markers for the overall force of gene flow. Gene flow largely affects all loci in the same way and hence information can be combined across alleles and loci to provide an overall estimate of the extent of gene flow. The methods cannot be reviewed in detail here. They are largely based on the theories of Wright (1931, 1978), who showed that the variance in frequency of a neutral allele is proportional to $1/(1 + 4Nm)$ where N is the population size and m is the dispersal rate. Hence Nm is the number of immigrants to a population and Wright’s results show that if Nm is much greater than 1, the variance among populations will be small, while if Nm is much less than 1, the variance will be large. Thus the variance in allele frequency or other statistics that depend on it can be used to estimate Nm and hence the importance of immigration for a species (Slatkin 1985).

Applying Wright's method to a variety of allele frequency data from natural populations has led to the conclusion that levels of gene flow differ greatly among species (Wright 1978; Slatkin 1985). As discussed above, many species, including many birds and other highly mobile species show little differentiation at apparently neutral loci, indicating that gene flow is an important force for them, while other species, including several species of salamanders and other sedentary species, show high levels of differentiation, suggesting that gene flow is relatively unimportant for them. Still other species, including such well-studied species as *Drosophila pseudoobscura*, a fruit fly found in the western United States, and *Euphydryas editha*, the checkerspot butterfly also found in the western US, are somewhat paradoxical. They exhibit little geographic differentiation over large geographical areas. Yet direct observations of their behaviour indicate that dispersal occurs over relatively short distances. Slatkin (1987) has used these and other examples to suggest that such species have only relatively recently colonized their current geographical ranges. The currently observed level of similarity among populations is not the product of ongoing gene flow but the result of the historical association of those populations before the expansion of their ranges. If this conclusion is true, then it points to an important problem in interpreting observations of natural populations, namely that they may not be at an equilibrium. What we see is the product of past events rather than ongoing processes. While it would be difficult to prove such a hypothesis in each particular case, it is important to bear that possibility in mind.

There is at present little empirical information available that allows us to test predictions about the genetic dynamics of metapopulations, and the widely publicized debate about whether cheetahs are devoid of genetic variation because of repeated bottlenecks in the total population (O'Brien and Evermann 1988), or because of a metapopulation structure (Pimm 1991), has been carried out in the absence of relevant data (see May 1995). Gilpin (1991) notes, however, that even if most species do not have a natural metapopulation structure, they may well behave in that way in the future if current rates of habitat destruction and fragmentation continue.

4.2.5 Summary

Genetic diversity within each species is the foundation of evolution and hence the foundation of the diversity of species. At the present time, there is extensive knowledge about the processes that affect genetic diversity but there is less knowledge about how diversity is maintained in each species. Based on the current knowledge in population genetics, we can draw a few conclusions that are relevant to the understanding of biodiversity. First, and probably most important, it is not possible to predict the response of

natural populations to a major change in the environment. Although there is abundant genetic diversity in most species for most characters, and hence the potential for a short-term response to selection, a species may respond to a change in conditions in a variety of ways that do not require genetic evolution. Furthermore, the longer-term response to selection is unpredictable even in laboratory populations. Second, in a widespread species there is the potential for substantial differences to evolve among local populations even if there is some dispersal of individuals among populations. To ignore those differences, some of which may drastically inhibit interbreeding, in attempts to manage populations might have undesirable consequences. Third, small population size increases the rate of loss of genetic diversity; and can lead to a substantial reduction in fitness, especially in outcrossing species. Finally, there are many genetic tools that can aid in the understanding and management of natural populations. New genetic markers are being discovered on a regular basis and they will be increasingly useful for understanding the history of natural populations and for understanding the forces that currently govern different parts of their genomes.

4.3 Diversification of species

The number of species, the distribution of species, and species extinction are at the centre of much of the global biodiversity crisis. Most often, appropriately or inappropriately, species diversity is the level at which biodiversity is assessed. Loss of biodiversity for many people means the loss of species, even though genetic and ecosystem diversity are, in fact, of equal or possibly even greater importance. This chapter examines the processes that lead to the formation of new species, discusses various concepts of species, and examines the evolutionary diversification of species.

New species can result from the gradual accumulation of genetic differences between lineages over long periods of time in response to selection for adaptation to different environments. Alternatively, new species can be formed by the precipitous and/or stochastic accumulation of genetic differences. Between these extremes lie many other possible modes of speciation. If one surveys a taxonomic diversity of organisms, it is clear that the formation of species occurs by many different mechanisms. Many groups of organisms have biological features that are either unique or singularly influential in their evolutionary biology. Thus, a mechanism of species formation may be rare in one group of organisms and be the most common mode of speciation in another group. A classic is that of polyploidy (the multiplication of chromosome number; see Section 2.2). Speciation due to polyploidy plays a minor role in animal evolution. In contrast, it is thought to be possibly the most important mode of speciation in higher

plants. This diversity of mechanisms, processes and patterns of speciation has lead to a corresponding diversity of species definitions. Often what one researcher considers a species is influenced by the group of organisms being studied. The definition of what constitutes a species remains controversial (see Section 2.1.4).

4.3.1 Population differentiation

The process of speciation must begin within an existing species. Two possible paths may lead to a new species. First, a gradual change of an entire lineage or metapopulation may occur in response to a changing environment. Such gradual change in an entire lineage is termed anagenesis (Figure 4.3-1a). Another possible mode of genetic change is cladogenesis, the branching of a lineage into two separate lineages (Figure 4.3-1b). Cladogenesis results in an increase in the number of species. Regardless of which course of species formation occurs, with rare exceptions the formation of new species begins with genetic change within the populations of a single species. Such population differentiation is often thought to occur by the gradual accumulation of genetic differences in response to natural selection. In nature each population within a species is confronted with a unique set of environmental conditions. Natural environments are a complex assemblage of physical and biological components such as temperature, moisture, light, competitors and predators. Natural selection works to adapt a population to the myriad components of its environment. Over the course of time, each population accumulates genes that confer adaptation to that population’s own unique combination of environmental parameters. The range for a single

environmental variable that a species encounters may be great and selection may adapt different populations to contrasting environments.

There are numerous studies in the evolutionary literature on adaptation to environmental variation. A classic case is the chromosomal inversions of *Drosophila pseudoobscura*. *Drosophila pseudoobscura* populations contain many different chromosomal inversions which occur in geographically localized regions. Intensive study of these inversions suggests that they contain a suite of genes which adapt the animals to multiple components of their specific environment. *Drosophila* populations show clear differentiation for these inversions, both on a geographical scale across the western United States, and along altitudinal gradients (Dobzhansky *et al.* 1977). A frequently cited example from plants is tolerance to heavy metal pollution. Plants of *Agrostis tenuis* in the British Isles occur both on mine tailings and in non-polluted pastures. Often these populations are contiguous, yet they show genetically based differences in tolerance to heavy metals (Bradshaw 1971). In *Agrostis* selection is only on one genetic locus, yet many other characteristics, such as plant size and flowering time, have also become differentiated as a correlated response to selection. Selection often results in a suite of genetic changes.

There are also numerous examples of selection producing functional diversity in many types of genes. The phosphoglucose isomerase genotypes of *Colias* butterflies differ dramatically in their biochemical properties and adapt the butterflies to varying temperatures (Feder and Watt 1992). In *Drosophila mercatorum*, an insertion in the 28S coding region of ribosomal DNA shows adaptive

Figure 4.3-1: Anagenesis versus cladogenesis. (a) Gradual change of an entire lineage. Such phyletic change is termed anagenesis. (b) The splitting of a lineage into two lineages. Such branching is termed cladogenesis.

divergence between populations along a moisture gradient. The insertion in rDNA results in a life-history change of increased pupal time which conveys resistance to desiccation (Hollocher *et al.* 1992). A well-documented example of geographical variation is the haemoglobin S allele in human populations of Africa and Asia which is based on adaptive resistance to malaria.

The preceding presents a traditional view of population differentiation. There are other modes of population differentiation and their general importance in genetic differentiation and subsequent speciation is debated. A powerful evolutionary force in small populations is random genetic drift. In small populations gene frequencies can be altered statistically due to small sample size (population size). If a species consists of small populations, one expects genetic differentiation among populations simply by random drift. A related process occurs when population size is drastically reduced in a bottleneck. Again, the episode of small population size may result in random genetic changes. Founder events are often affected by genetic drift. In many instances populations are founded by a small sample of individuals from another population. All genes in the new population stem from the founders of that population and often are not an accurate representation of the alleles or frequencies of the source population. Thus the source and derived populations may have significant but random differences in gene frequency. Experimental work with small populations of *Drosophila* has documented the role of drift in altering gene frequencies. Founder events have played an important role in human genetic diseases such as Tay-Sachs and Huntington's chorea. Finally, studies of genetic variation in nature suggest that in some cases drift shapes population structure. In many species of both plants and animals with small population sizes, allozyme data show statistically significant but apparently random variations between populations with little variation within populations. Such apportionment of variation is consistent with genetic drift, which decreases variation within populations while increasing variation between populations.

Populations are not influenced only by single evolutionary forces. Most species will have within their geographical ranges, or in their history, populations of small size. Likewise, the environment is always placing selective constraints on the genetic variation within populations. Wright (1970) proposed the shifting balance theory of evolution which considers the interaction of multiple evolutionary processes. Populations are thought to exist in an 'adaptive landscape', in which peaks of high fitness are separated by valleys of low fitness. In the shifting balance theory Wright considered the deterministic processes of migration, gene flow and selection and how they interact with the stochastic process of genetic drift. If a population is on an adaptive peak, genetic drift may carry

gene frequencies in the population downhill, against selection, into a valley of low fitness. Selection for increased fitness may then bring the population back uphill along the slope of a different and potentially higher adaptive peak with greater fitness. Genetic drift and selection act in concert to reach a high fitness, beyond what selection can do by itself. In the shifting balance theory, the genetic composition of a population moves from adaptive peak to adaptive peak. This process continues until an optimal genetic composition for many loci is reached within the population.

The biogeographical history of a species can also have a strong influence on genetic differentiation among populations. Glacial refugia and subsequent postglacial migration have influenced the pattern of genetic variation of temperate taxa. Many plant and animal species of Europe show a genetic discontinuity between Eastern and Western Europe. In a recent study of oak trees, variation in a chloroplast *tRNA*^{luc} intron which is highly conserved shows the same geographical discontinuity across Europe as is seen for other species and for other genes (Ferris *et al.* 1993). These data strongly suggest that oaks in Europe were colonized from two different glacial refugia and that the genetic discontinuity in a conserved DNA sequence is due to historical biogeography.

So far, we have considered populations as isolated, independent units, yet few species contain populations that are always clearly demarcated from each other. All species and populations are patchy in distribution at some scale. Populations in the same geographical area interact with each other by migration of individuals and by gene flow (Chapter 4.2). Consequently, genetic differentiation in many species occurs at a higher level – that of the metapopulation. A metapopulation is defined as a population of populations (see also 4.4.2). Metapopulations are in many cases the relevant biological unit for both population genetic processes and ecological processes. Both demographic and genetic attributes are affected by the metapopulation. In an ecological sense population size is determined by birth and death rates of individuals which can be affected by migration from the components of the metapopulation. Metapopulations are determined by the rates of establishment and extinction of component populations which are affected in turn by migration by individuals. At a genetic level, gene flow among the components of a metapopulation works to reduce genetic differentiation. In populations of oak trees discussed above, metapopulations are united by migration and little genetic differentiation occurs except at the margin of metapopulations derived from different glacial refugia.

When systems of metapopulations become differentiated, they often take on a separate biological status such as subspecies or races. In some cases these genetic differences can be profound and the subspecies or

Figure 4.3-2: Phyletic gradualism versus punctuated equilibrium. Both figures show the same ancestral phenotype and the same phenotypic diversity in the end points. The rate of change illustrated by phyletic gradualism (a) is fairly constant over time, although lineages may differ. Punctuated equilibrium (b), on the other hand, is characterized by lengthy periods of very little phenotypic change interrupted by period of very rapid change.

race may be a separate evolutionary lineage. In other cases, a taxonomic name may be given to a morphological or colour variant and may represent merely different gene frequencies.

At this point populations or metapopulations are genetically differentiated. The next step in the diversification continuum is the species level, or speciation. There is much controversy about how evolution proceeds during speciation events. A long-standing hypothesis is that of phyletic gradualism. In phyletic gradualism the same micro-evolutionary processes that lead to population differentiation and adaptation continue, causing ever-increasing divergence between populations. At some point, enough divergence is accumulated for the differentiation to reach the level of species. In phyletic gradualism, evolution proceeds at nearly the same rate before, during and after speciation (Figure 4.3-2a). New species arise by the slow transformation of ancestral populations. The process of phyletic gradualism is implicit in Darwin’s work, where he uses the concept of uniformitarianism to extrapolate from the process of natural selection to account for all of evolution including speciation and the formation of higher taxa. The pervasive view from the Neo-Darwinian synthesis is that most evolutionary transition takes place within established species; the branching process of cladogenesis adds new lineages but accounts for a relatively small amount of large-scale evolutionary change (Stanley 1979; Eldredge 1989).

Beginning in the 1970s, an alternative hypothesis of evolutionary rates and speciation was proposed – that of

punctuated equilibrium (Eldredge and Gould 1972; Gould and Eldredge 1977). The fossil record shows long periods of time when species remain relatively the same with little morphological change. At other times there appears to be rapid morphological evolution and speciation. Based on this common pattern in the fossil record, Eldredge and Gould (1972) proposed that evolutionary rates are not constant over time. They propose that for the most part, little evolutionary change occurs within species, and that the genetic changes associated with population-level phenomena do not account for species differences. Rather, most significant evolutionary change is associated with the event of speciation. The rate of evolution is accelerated by rapid divergent speciation. Between these ‘punctuations’ are periods of time with little or no evolutionary change; species are near equilibrium and experience periods of stasis (Figure 4.3-2b).

These two views are at opposite ends of a continuum of possible evolutionary changes. In many cases evolutionary rates are most likely somewhere in between, with periods of rapid and slow evolution and with periods of phyletic evolution and cladogenesis. But, regardless of the tempo or mode, the evolutionary process occurs and new species are formed.

As biologists learn more about the evolutionary process and species differences, the concept of what constitutes a species is becoming increasingly difficult (see Section 2.1.4). This must be borne in mind when considering the ways in which speciation takes place.

4.3.2 Speciation

The pivotal event in the proliferation of biotic diversity occurs when a new species comes into being: the process of speciation. This event must include enough divergence from other forms to allow diagnostic determination of the distinction between the new species and others. And under the biological species concept, the hallmark of this event is the acquisition of reproductive isolation (see Section 2.1.4). In the discussion here, we will outline the paths by which such barriers to interbreeding may arise between two groups, leading to speciation in this sense.

The commonly cited models of speciation include *allopatric* (geographic) speciation, where populations diverge while spatially separated; *parapatric* (semigeographic) speciation, where adjacent but non-overlapping populations diverge; and *sympatric* speciation, where differentiation occurs with no spatial separation or distinction between incipient species. In addition, since speciation is a genetic event as well, models must accommodate a genetic basis for speciation.

4.3.2.1 Allopatric speciation

Traditional models of geographic speciation have been well articulated by a number of insightful evolutionary biologists (Dobzhansky 1970; Mayr 1963; Grant 1963, 1981). These models all view the starting point as geographically isolated populations which may then progress through the stages of primary divergence (Figure 4.3-3; Grant 1963). If there is geographic isolation of two

populations (A and B in Figure 4.3-3) during some period, such that there is no gene flow between these populations, then these populations are in essence reproductively isolated although the barrier is geographic rather than genetic. If, over time, populations A and B diverge genetically to the point that they are diagnostically differentiated, then they might be recognized as subspecies or semispecies. When the lineages have diverged genetically to the point that they are no longer interfertile, they are then intrinsically reproductively isolated and this model would grant species status to each group. At this point geographic separation would no longer be relevant to the evolutionary fate of the two taxa. Reproductive isolation will remain even with the removal of geographic barriers.

The geographical barriers required for allopatric speciation may take many forms – mountain ranges, deserts, canyons, ocean basins and the like. Many examples of geographic speciation are known from oceanic islands near mainlands where populations can become *peripheral isolates*. An oft-cited example is provided by kingfishers on the mainland of New Guinea and nearby islands (Mayr 1942). The forms of *Tanysepta galatea* on the mainland comprise three fairly indistinguishable subspecies. Five island forms of *T. galatea*, however, are quite distinct, and were originally described as separate species. The related *T. hydrocharis*, which today occupies both the mainland and an island, is believed to have reached its status as a separate non-interbreeding species while peripherally isolated from the mainland forms of *T. galatea* (Mayr 1942).

Figure 4.3-3: Stages of phenotypic divergence. In the diagram, the separation and divergence of two lineages over time is illustrated. Both lineages descend from their common ancestral population A'. While geographically separated, populations diverge to the point at which they are recognized as geographical races A and B, and perhaps after further divergence semispecies status is achieved. The heavy vertical line suggests geographical separation forms a barrier to gene flow between the diverging populations, although they remain interfertile. By the time the diverging lines are recognized as species A and B, the populations may still be geographically separated, but they are no longer interfertile. The geographical barrier to gene flow is no longer essential to maintenance of the divergent characteristics. Over time, the lineages may diverge to the point at which they are recognized as different genera, but that is not necessarily a consequence of geographic speciation. (Redrawn with modifications from Grant 1963.)

4.3.2.2 Parapatric speciation

In parapatric models of speciation, adjacent populations between which gene flow is possible diverge to the point of becoming separate species. The distinction is that there is no substantial geographic barrier to interbreeding between the two populations. For this divergence to occur, selection must favour alternative alleles in the adjacent populations, even in the face of possible gene exchange. As selection proceeds, distinct populations can be recognized, and where they are in contact a hybrid zone may be present. With sufficiently strong selection, differentiation may proceed to the point that populations are reproductively isolated, and they may be recognized as species meeting the isolation criterion of the biological species concept.

Some evolutionary biologists (e.g. Mayr 1970) believe that parapatric speciation can be viewed as a process of improving, in zones of secondary contact, imperfect isolating mechanisms that were acquired allopatrically. One commonly cited example is the narrow contact zone in Europe between the hooded crow (*Corvus corone*) to the west and the carrion crow (*C. cornix*) to the east. Although they interbreed and produce hybrids at the zone of contact, the forms remain distinct throughout the rest of their ranges. White (1978) cites several examples of what he terms clinal speciation, where parapatric speciation seems evident and there is no evidence of earlier periods of allopatry. We certainly know of cases of selection strong enough to lead to differentiation in adjacent populations. Perhaps the clearest cases are those involving evolution of heavy metal tolerance in plants on mine tailings despite gene flow from non-tolerant populations adjacent to the tolerant populations (Bradshaw 1971).

4.3.2.3 Sympatric speciation

In theory, a single species can give rise to two species completely within the original range of the ancestral species. Some of the ways this might happen are more controversial than others. One fairly non-controversial mode is via polyploidy, which may lead to 'instantaneous' speciation. This may be common among plants, and it will be discussed further below. But most of the theoretical models that allow sympatric speciation are based on disruptive selection (e.g. Maynard Smith 1966), and there remains considerable scepticism over whether the theoretically possible has been shown actually to occur (e.g. Paterson 1981; see 4.2.3.3).

One sort of example cited frequently as demonstrating sympatric speciation involves shifting host plants by phytophagous insects. Bush (1969) suggested that sympatric speciation was being observed in the fruit fly *Rhagoletis pomonella*, which has hawthorn as its native host in North America. It was first observed infesting introduced apples in 1864, and in this century it began to infest cherries. In Bush's explanation, as few as two genes

may be involved in host selection and survival, and selection can lead to host races separated by differing host preference, development and emergence times, and mating periods. However, Paterson (1981) has argued that sympatric speciation remains a theoretical concept without support from critically observed facts.

4.3.2.4 Other modes of speciation

Allopolyploidy is an important source of new species among plants. A starting point might be hybridization between two diploid species, with chromosome sets AA and BB, for example. The hybrid with non-homologous chromosome sets AB would typically be sterile due to meiotic failure resulting from the lack of chromosomal homology. But, if the chromosome number in the hybrid is doubled, the tetraploid composition would be AA BB. Since each chromosome is present as a homologous pair, normal meiosis is possible, and fertility may be achieved. Back-crosses to the original parental taxa would yield sterile triploids, so the new tetraploid is effectively isolated genetically from its progenitor species. Allopolyploidy is generally believed to be widespread in the plant kingdom. Grant (1963) reported 43% of 12 000 dicotyledon species and 58% of 5000 monocotyledon species were polyploid, suggesting that such a mechanism of species generation may be very important among plants.

Stasipatric speciation is the term used by White (1978) for changes in chromosome complements via rearrangements within the area occupied by an ancestral species. Such rearrangements can be extensive and result in reduce fertility when heterozygous. Populations homozygous for novel arrangements will become isolated from original populations. An example White cites involves dozens of chromosomal fusions and fissions among the more than 200 species in the Australian grasshopper subfamily Morabinae (White 1978). However, some workers feel that such multiple rearrangements typically arise allopatrically (Futuyma 1986).

Macrogenesis, the sudden appearance of a new species as the result of some type of saltational (rapid) macromutation conferring reproductive isolation, has from time to time been proposed as a mode of speciation. The proposed mechanism involves some type of revolutionary mutation which might produce what Goldschmidt (1940) has called a 'hopeful monster'. We do know of such changes in homeotic mutants of *Drosophila* like bithorax and aristapedia. However, as Mayr (1963) pointed out, most such mutants are 'hopeless'. Such macrogenesis is generally disregarded today.

Speciation in **asexual taxa** is an interesting concept. Since most models of speciation require some type of shift and stabilization of the genetic system involved, it is relevant to question how to evaluate speciation in asexual organisms. Like sexual organisms, asexuals have ancestor-descendent genetic continuity in lineages. Obviously, reproductive isolation is moot, since each lineage is

eternally isolated (except for exchange mechanisms such as plasmids). Mutation, selection and drift must be responsible for most of the diversity we observe today in organisms ranging from bacteria to obligately asexual fungi and plants. The phylogenetic and cohesion species concepts easily accommodate asexual taxa, since they do not depend on identifying reproductive boundaries to recognize that speciation has proceeded.

4.3.3 Multiplication of species

Charles Darwin's *On the Origin of Species* actually considers five different processes or theories of evolution (Mayr 1970). One of the central components of his work is the concept of multiplication of species. The branching of evolutionary lineages, cladogenesis, is the process that results in an increase in species biodiversity. Clearly the number of species has varied over geological time, both in an absolute sense and within specific taxonomic groups. For example, the diversity of marine animals has varied dramatically throughout the geological record (Sepkoski 1981, 1984; see Section 4.1). Some groups, such as starfish, have increased their diversity, and then remained constant. Other groups such as sea urchins, have had rapid increases in the number of species, then a decline in species numbers, and then another subsequent increase. Diversity is a function of both the speciation rate and the rate of extinction. If one examines the fossil record, periods of mass extinction are followed by a rapid increase in diversity. Here we will examine the processes that result in the formation of more species. Specifically, we address the issue of why evolutionary lineages branch. The other relevant process for species diversity, extinction, is discussed elsewhere in this volume.

Patterns of taxonomic diversification have generally been explained within an adaptationist framework. A major component of such explanations is the concept of a key innovation – a new character or structural/functional complex that may characterize a cluster of species. This cluster of species is often a clade, or a monophyletic group. Key innovations are a new way of making a living and are thought to be causally related to the subsequent success of the group possessing them. Key innovations allow a species group to occupy a novel suite of niches from which the group was previously excluded. That is, the species group can move into a new adaptive zone (Simpson 1944). The key innovation gives a species access to multiple new niches: cladogenesis and speciation occur as evolution adapts populations to these multiple niches. Closely associated with the concept of key innovation is the process of adaptive radiation, the rapid proliferation of species from a single ancestral lineage, often associated with the occupation of a new adaptive zone. Simpson (1944) considers adaptive radiation as the source of most large-scale morphological transitions and evolution.

Classic examples of key innovations include the bony skeleton of vertebrates, avian flight, the large brain of hominids, insect wings, and insect pollination in angiosperms. One of the most interesting cases of increase in diversity occurs in the cichlid fishes of African lakes. Liem (1973) in a classic study determined that a few modifications of the jaw apparatus of cichlid fishes comprised a key innovation that allowed cichlids to adapt and specialize on a variety of food types in numerous aquatic habitats. Rapid and frequent speciation occurred as these niches were filled.

Lineages may enter an adaptive zone and proliferate there because of the evolution of a key innovation, or the lineage may be pre-adapted to the adaptive zone. Key innovations are not necessary for adaptive radiation. When a whole suite of unoccupied niches is opened to a lineage, such as on islands, very rapid species proliferation may occur. The species of finch that first colonized the Galapagos Islands did not have a key innovation, yet produced perhaps the most famous adaptive radiation (Grant 1986). Cracraft (1990) has criticized the widespread interpretation of evolutionary innovations as a causal factor in adaptive radiation. For example, flight is often interpreted as a key innovation but is actually an aggregation of many morphological and physiological innovations which must have evolved at different times (Cracraft 1990). The multitude of flight innovations were occurring at the same time as diversity was proliferating and therefore could not be responsible for the evolutionary proliferation of birds. Recently molecular methods have been applied to the study of key innovations. The evolutionary success of flowering plants has been attributed to key innovations that originated at the base of the angiosperm clade. Sanderson and Donoghue (1994) used maximum likelihood methods to assess whether increases in the rate of branching were correlated with origin of supposed key innovations such as accelerated life-cycle and rhizomatous habit. From their analysis, large increases in branching rate did not occur until after the putative key innovations of angiosperms had evolved, suggesting that key innovations were not responsible for the adaptive radiation of angiosperms.

One other aspect of adaptive radiation needs to be considered, and that is the relationship between the extinction of one group and the rise of another. An example of this process is the rapid divergence of early mammals into the niches vacated by the extinction of dinosaurs. As with the dinosaurs and mammals, the rise of one taxon is often connected with the decline of another. Such a relationship suggests that competition plays a role in adaptive radiation and speciation. Why should one group replace another?

Ecological replacement of one group by another ecologically equivalent group has been used as evidence of

competitive exclusion of one group by another. That is, the dinosaurs kept the mammals suppressed until the dinosaurs became extinct. Then mammals were released for competition and were free to radiate. Such common scenarios have rightly come under criticism (Futuyma 1986). It is incorrect to assume that the decline of one group caused an increase in another, merely because of temporal sequence. The evolution of crocodiles provides a good example (Colbert 1949). Crocodiles invaded their niches after the phytosaurs had become extinct, and only after occupying these niches became increasingly adapted to aquatic life. Thus, there was no suppression of the crocodiles by competition with the phytosaurs, since the crocodile lineage did not occupy the same niches as the phytosaurs at the time they were both extant. On the other hand, angiosperms have replaced gymnosperms and pteridophytes as the dominant group of terrestrial plants. In the fossil record one observes a strikingly parallel decline in conifers as angiosperms diversify, suggesting but not proving a role for competition in speciation.

4.3.4 Summary

The formation of species occurs by a number of different mechanisms, and this diversity of mechanisms has led to a corresponding diversity of species concepts which poses a pragmatic problem for conservationists. Which species concept is most appropriate to use, especially when evolutionary biologists themselves disagree? The use of a particular species concept is often based on the biological characteristics of a group of organisms. Thus, the determination of what exactly constitutes a species is, in many cases, best left to the biologists who study a taxonomic group.

Although many of the processes which lead to new species are debated, several points emerge. The formation of new species and the adaptive radiation of lineages have a strong ecological context. Speciation occurs predominantly as a result of adaptation either to a new environment or to a changing environment. The greatest rates of cladogenesis are all associated with the occupation of new adaptive zones. And if we take this argument one step further, species persist by maintaining adaptation to their ecological niches. The role of the environment is central to the formation of, and to the maintenance of, species diversity. Conservation of global biodiversity must centre on the conservation of habitats, so as to preserve not only species, but also the processes that lead to the formation of species.

4.4 Ecology of extinctions

4.4.1 Current rate of extinctions

In the public debate about biodiversity, it is often remarked that no species will survive forever. The other side of the coin is that every species is a unique potential ancestor of

new species, hence accelerated extinctions have profound consequences for the evolution of life on Earth. In the history of life, disappearance of species and higher taxa has been compensated for by the evolution of new forms from the existing ones (Chapter 4.1). The rates of extinction and speciation have varied greatly, but not always in parallel: the palaeontological record includes periods of net decline, and of net gain, in biodiversity (Chapter 4.1).

Our current concern about biodiversity stems largely from the judgement that the present rate of species extinction is extremely high in comparison with the natural average ('background') rate. The latter is so low that 'no biologist has documented the extinction of a continental species of plant or animal caused by non-human agencies such as competition, disease or environmental perturbation in situations unaffected by man' (Soulé 1983). The average species lifetime of mammals in the fossil record is in the order of one million years (Martin 1993), which would give roughly 0.5 extinctions per 100 years for the present mammalian fauna of nearly 5000 species. As will become apparent below, the current rate of extinction of mammals is roughly 100 times higher than this background rate. In other taxa the discrepancy may be even greater.

4.4.1.1 Past extinctions

Over geological time, among groups for which there is an adequate fossil record (the record is best for marine animals, but includes microbes, algae, fungi, protists, plants and terrestrial animals), species diversity has increased since life first arose nearly 4 billion years ago (Wilson 1988a; Benton 1995; see Section 4.1). However, this growth has been interrupted on numerous occasions by significant periods of species extinction including five 'mass extinctions' (Sepkoski 1992a; see Section 4.1). The largest of the mass extinctions, which took place at the end of the Permian (250 Ma ago), eliminated between 77% and 96% of marine animal species preserved in the fossil record (Valentine *et al.* 1978; Raup 1979b). The most recent mass extinction took place 65 Ma ago at the end of the Cretaceous, when the dinosaurs died out, and resulted in the loss of approximately 10% of families of terrestrial organisms and 15% of families of marine organisms. Even apart from these mass extinctions, 'background' rates of extinction are not constant. For example, during the past 250 Ma, relatively high rates of extinction are thought to have occurred nine times. Two of these nine episodes were mass extinctions: that of the late Triassic, 220 Ma ago, and that of the late Cretaceous (Sepkoski and Raup 1986).

Among organisms with adequate fossil records – including mammals, diatoms and some invertebrate groups – the average 'life-span' of a species is in the order of 5–10 Ma (Raup 1978; May *et al.* 1995). If this were to be applied to our estimate of approximately 13.5 million species of all groups currently alive, this would suggest that the expected

current rates of extinction would be very roughly one to three species per year (cf. May *et al.* 1995). There is, however, uncertainty about the average ‘life-span’ of species in the fossil record and there is variation in life-span estimates for different groups of organisms. For mammals, with an average lifespan of approximately 1 million years (Martin 1993), one extinction among the approximately 5000 mammal species on Earth would, on average, be expected approximately every two centuries. Among organisms with restricted ranges, prehistoric extinction rates may have been higher than the averages suggest, but for widespread species the ‘background’ extinction rate – that is, the average rate of extinction – is extremely low.

Humans have been a cause of species extinction for thousands of years. Significant extinctions of large mammals in the Americas and Australia took place between 15 000 and 35 000 years ago as humans first moved into these continents (Martin 1973, 1986). And prehistoric colonization of islands in the Pacific and Indian Oceans some 1000 to 2000 years ago by humans and their commensal animals such as rats, dogs and pigs may have led to the extinction of as many as one-quarter of the world’s bird species (Olson and James 1982; Vitousek 1988; Olson 1989). On tropical Pacific islands alone, more than 2000 species of birds may have been driven to extinction, representing a 20% world-wide reduction in bird species (Steadman 1995).

4.4.1.2 Recent extinctions

Species are recorded by the World Conservation Monitoring Centre as ‘extinct’ (Ex) based on the criteria given in the IUCN (*Red Data Book*) categories of threat: they are taxa that are no longer known to exist in the wild after repeated searches of their type localities and other known or likely places. As applied to animals, following a resolution of the CITES Conference of the Parties in 1979, a species is recognized as extinct when it has not been found for at least 50 years, although this is not always applied rigorously. Moreover, in some instances, when the last few individuals of a species are being monitored closely, an extinction may also be recorded when the last individual dies. This means that our current records for species extinctions do not include all actual extinctions that may have taken place in recent decades. On the other hand, every year cases are reported of species thought to have been extinct being rediscovered, partly through imperfect exploration of the areas concerned (cf. Magsalay *et al.* 1995). It is immensely difficult, therefore, to know when the last individuals of a species, especially very small ones (such as insects and fungi) have disappeared. The use of statistical models derived from the capture–mark–recapture theory may provide better estimates of species extinction and colonization (Nichols and Pollock 1983; Clobert 1995),

in particular because it provides a way to correct for differences in intensity of area exploration (capture probability).

Since 1600, 484 animal and 654 plant species (mostly vertebrates and flowering plants) are recorded as having gone extinct according to data compiled by the World Conservation Monitoring Centre (Table 4.4-1), although this is certainly an underestimate of the true total, particularly with regard to tropical species. The rate of recorded extinctions in groups such as birds and mammals has increased dramatically during this period. Nearly three times as many species of birds and mammals were recorded as becoming extinct since 1810 (112 species), as were recorded as going extinct between 1600 and 1810 (38 species) (WCMC 1992). Geographically, extinctions during this period appear to have been most numerous on islands, island archipelagos, and in freshwater ecosystems. Among animals, for example, 75% of extinctions took place on islands (WCMC 1992). Freshwater systems are the terrestrial analogue of oceanic islands and are also particularly vulnerable to habitat loss and to the introduction of non-native species. Recorded extinctions in aquatic environments are predominantly from freshwater lakes and rivers.

The smaller the area and the more severe the environmental change the higher the rate of local loss of populations of species. For example, the Netherlands has an area of 35 000 km², a human population of 15 million, 5 million cattle, 15 million pigs and 100 million chickens (Anon. 1991). Of the higher plants, 37 of 1410 species went extinct in the Netherlands by 1940, and another 33 species were extinct by 1990. The proportions of nationally extinct species among grasshoppers and crickets, dragonflies, butterflies, breeding birds and mammals were 2%, 13%, 24%, 2% and 7%, respectively (Bink *et al.* 1994).

Table 4.4-1: Number of recorded species extinctions since 1600 (WCMC 1992; WCMC pers. comm. 15 February 1995).

Group	Number extinct since 1600
Molluscs	191
Birds	115
Mammals	58
Other animals	120
Total Animals	484
Plants	654

Considerable uncertainty surrounds any attempt to compare recent extinction rates with rates calculated from the fossil record. Quantitative palaeontological data are best among marine invertebrates (a group that is poorly documented today). Fossilized species are usually drawn

Table 4.4-2: Numbers of species considered ‘Threatened’ by the World Conservation Monitoring Centre. (WCMC classifies all species listed as ‘Endangered’, ‘Vulnerable’, ‘Rare’ or ‘Indeterminate’ as threatened species.) (WCMC pers. comm. 1995.)

Threatened	Endangered	Vulnerable	Rare	Indeterminate	Total
Mammals	177	199	89	68	533
Birds	188	241	257	176	862
Reptiles	47	88	79	43	257
Amphibians	32	32	55	14	133
Fishes	158	226	246	304	934
Invertebrates	582	702	422	941	2647
Plants	3632	5687	11485	5302	26106

from the more abundant and widespread taxa, and time resolution is rarely better than 10³–10⁴ years (Jablonski 1995). Moreover, mean durations of fossil species vary by more than an order of magnitude even within clades. Thus average ‘background’ rates of extinction conceal considerable variations in rates among different groups and considerable variation in rates over time. Additional uncertainty in comparative estimates results from the fact that records of recent extinctions are almost certainly under-recordings even for groups such as plants, birds and mammals.

Given these caveats, however, recent rates of extinction are still strikingly higher than rates in the fossil record. If we accept the measured background rate of roughly one extinction of a mammal species on average every 200 years, the 20 recorded mammal extinctions this century represents a rate of extinction 40 times greater than the ‘average’. Assuming that the average species lifespan of birds falls within the average range of 5–10 million years, the more than 2000 extinctions that have taken place in the last 2000 years associated with human actions is a rate approximately 1000 times greater than the ‘background’ rate of extinction.

4.4.1.3 Current status and rate of extinctions

The most comprehensive source of information on extinctions and threats of extinction are the statistics on threatened species published in the *Red Lists and Red Data Books* compiled globally by the World Conservation Monitoring Centre (see Sections 7.2.8.3.2 and 13.4.3). Various systems exist for classifying the status of species with respect to their long-term probability of survival. The categories of threat for species, introduced by IUCN nearly 50 years ago, are widely used around the world although new IUCN Red List categories were introduced by IUCN in 1994 (IUCN 1995). A threatened species refers to a species considered to fall within one of the categories of threat (Extinct, Endangered, Vulnerable, Rare, Indeterminate) and in general terms can be considered to be

a species thought to be at significant risk of extinction in the foreseeable future because of random or deterministic factors affecting its population size or by virtue of its rarity. The numbers of species listed as threatened are minimum estimates, since species are listed only if enough is known about their population size, trends and potential threats to allow judgement of their status.

The estimates for the minimum numbers of globally threatened animal and plant species in 1994 are 5366 animals and 26 106 plants (Table 4.4-2). For individual groups, 11% of birds, 18% of mammals, 5% of fish, and 8% of plants are threatened. However, for the vast majority of the 1.75 million described species, and the many millions of undescribed species, no assessment of status has been made due to a lack of information.

Many threatened species are found on islands and in freshwater ecosystems. For example, one in three of all known threatened plants are island endemics. Among birds, some 23% of island species are threatened, compared with only 11% of birds world-wide (WCMC 1992). Other regions with particularly high levels of threat include the Mediterranean-climate regions. As a result of recent habitat change, introduced species, and the high degree of local endemism of plants in Mediterranean regions, an estimated 15% of vascular plants are threatened in the Mediterranean zone of California, 17% in the Cape Province of South Africa, and 24% in southwest Australia (Reid and Miller 1989), varying with the time of human implantation (Greuter 1995).

An important point that is emerging is that environmental changes, whether human-induced or not, are likely to have less impact on floras and faunas that have undergone similar stresses in the past. Thus Pimm et al. (1995a) show that there was lower recent extinction of birds in the islands of the western Pacific, which were colonized by humans some 3000–5000 years ago, than on the more recently colonized Hawaiian and other eastern Pacific islands. Also, Greuter (1995) has shown that records of recent plant extinctions in regions with a

Mediterranean flora are lowest in the Mediterranean proper (0.1%), where human impacts are oldest and higher where the impacts are more recent (the Cape Region – 0.3%; California – 0.4% and Western Australia – 1%)

For those groups of species for which sufficient data are available, including beetles, birds, vascular plants and mammals, the number of species found in a given habitat has been found to depend on the area of the habitat (Connor and McCoy 1979; Reid 1992). The empirical relationship between number of species and area for these groups, known as the ‘species–area’ relationship, can be used to project impending rates of extinction due to habitat loss. These estimates suggest the likely percentage of species within these groups that will eventually become extinct in a region as a result of habitat that has already been lost or that is projected to be lost. This reduction in equilibrium numbers is often referred to as the percentage of species ‘committed to extinction’ (Reid 1992; Heywood and Stuart 1992; Heywood *et al.* 1994; Magsalay *et al.* 1995) in the sense that these extinctions may not be immediate. In fact, it could take decades or even centuries for the reduced habitat to reach its ‘equilibrium’ number of species, and as Simberloff (1992) notes, there is no accepted theory for the rate at which species will be lost through time and the new equilibrium reached.

Because not all extinctions due to habitat loss take place immediately, the recovery of habitats before a new equilibrium number is reached can prevent some extinctions (Reid 1992; Heywood and Stuart 1992). For example, despite the reduction of the Atlantic forests (‘Mata Atlântica’) of Brazil to around 10% of their original extent over the past century, only a handful of species are known to have become extinct (Brown and Brown 1992), although many are reduced to small populations and are therefore susceptible to imminent extinction.

Species–area estimates of extinction rates give some indication of the long-term consequences of habitat loss, but they are imprecise due to uncertainty in: (1) rates of habitat loss; (2) likely survival of species in modified habitats; (3) detailed knowledge of the distributions of species and endemism (cf. Pimm *et al.* 1995b); (4) the influence of the pattern of habitat loss on species survival (fragmentation could result in greater impacts (Simberloff 1992) while the protection of certain critical habitats could greatly reduce impacts); (5) the variation among taxonomic groups in the relationship between species numbers and area; (6) past disturbance or habitat loss (residual losses of species may occur due to the habitat loss that took place recently, or rates may be lower than expected because of previous disturbance that caused the extinction of sensitive species); and (7) future changes in human behaviour or resource management that could ameliorate or exacerbate these effects (Reid 1992; Heywood and Stuart 1992).

A number of estimates of extinction rates in tropical forests have been made using species–area curves (Lovejoy

1980; Simberloff 1986; Raven 1987; Myers 1988; Wilson 1988b; Reid and Miller 1989; Reid 1992; reviewed in Reid 1992). Estimates of species that will become extinct or committed to extinction in tropical forests over approximately the next quarter century range from 2% to 25% in the groups examined (variously: plants, birds, plants and birds, and all species). The wide range in these estimates stems from different assumptions about future rates of forest loss and proportion of species diversity in tropical forests, use of different estimates for the slope of the species–area curve, and differences in the types of tropical forests considered. For example, considering only closed tropical forests at rates of loss measured in the late 1980s (approximately 10 million hectares per year, or just under 1% of closed tropical forest area per year) the equilibrium number of species would be reduced by 4% to 8% over the next quarter century (Reid 1992).

Because of the potential added impact of forest fragmentation on rates of extinction, these estimates may be conservative (Simberloff 1992), although if rates of forest loss decline during the next 25 years they could be over-estimates. They are likely to be most accurate for groups such as beetles, birds, plants and mammals for which empirical data on species–area curves are available. It is unlikely that the species–area relationship does not apply equally well to less well studied groups; however, it is likely that extinction estimates would differ across lesser known groups. For example, forest-canopy-dependent invertebrates might face greater threats from forest loss than soil-dwelling invertebrates or microorganisms. Estimates of species loss in tropical forests depend strongly on predictions of future rates of forest loss and in particular on the capacity and will of the countries concerned to act on deforestation and forest fragmentation (Simberloff 1992). Comparable estimates have not been made for the potential impact of habitat loss in other regions.

A rough idea of the global impact of these predicted tropical forest extinction rates can be made based on evidence that species diversity in tropical forests accounts for roughly one half of the world’s species diversity (Myers 1980; Reid and Miller 1989). The published range of tropical forest extinction estimates thus suggests that roughly 1–10% of the world’s species will become extinct or committed to extinction in the groups examined (plants, birds, plants and birds, and all species) over the next quarter century. These rates of extinction would be approximately 1000 to 10 000 times the average expected ‘background’ extinction rates.

Two alternative approaches to projecting rates of species extinctions give comparable estimates of impending extinction, based on data obtained from lists of species ‘Threatened’, ‘Vulnerable’, ‘Endangered’, ‘Probably extinct’ and ‘Extinct’ in international assessments. One method examines the rate at which individual species are

moving to progressively more threatened categories (Smith *et al.* 1993). For birds and mammals, the current rate at which species are moving into more threatened categories implies that 50% of the species in the groups will be extinct within 200–300 years (Smith *et al.* 1993). The second method examines species-by-species assessments of extinction probability distributions as a function of time (Mace 1995). Based on this approach, 50% of species in selected subsets of mammals, birds and reptiles are projected to be extinct within 100–1000 years. Extinction rates calculated with either of these methods are imprecise, since the numbers of species in various categories and changes in the status of species reflect not only biological factors but also the state of knowledge of the species involved, levels of human concern about the taxa, and rates of data entry.

The extinction of a species is generally due to multiple causes: no single threat to populations or species can be considered independently (see 4.4.2.3). For example, the loss of habitat may reduce the population of a species to a size small enough to be at risk from predation, disease or severe weather. The cumulative effect of various disturbances can seriously threaten a region's biodiversity. Even if the disturbances have only additive effects, small changes can add up to serious impacts.

Based on ecological theory, species that are most threatened with extinction are: (1) large organisms, (2) those highest on the food chain, (3) those with small population sizes, (4) those with small ranges or distributions, (5) those tied in some aspect of their biology to habitats or ecosystems that are threatened, (6) those that have evolved in isolation (e.g. island faunas and floras), (7) those with poor dispersal and colonization abilities, (8) those with colonial nesting habits, (9) migratory species, (10) those dependent on unreliable resources, and (11) those with little evolutionary experience of disturbances. Thus, many island and locally endemic plants and animals will be lost because of their susceptibility to habitat loss, and extinctions among top carnivores and large animals will be disproportionate because their population density is generally low (Reid and Miller 1989).

4.4.2 Mechanisms of extinction

Here we review the mechanisms of population extinction. Why does a population go extinct under the prevailing environmental conditions? Later (4.4.3) we turn to the *causes* of extinction. Why do populations become vulnerable to extinction? This latter question is generally related to various forms of environmental change. Instead of population extinction we may inquire about species extinction, recognizing that a species goes extinct when the last population goes extinct.

A population goes extinct with certainty if, in the long run, the death rate exceeds the birth rate (MacArthur and

Wilson 1967; Richter-Dyn and Goel 1972; Peters and Mangel 1990). Whatever causes population extinction (4.4.3), this process involves an increase in death rate, a decrease in birth rate, or both. A more subtle and challenging task is to understand the risks of extinction in environments in which, in principle, the population may persist forever (birth rate exceeds death rate at low density). We shall first discuss extinctions in the context of single populations, then move on to consider extinctions in metapopulations, systems of several connected local populations (Gilpin and Hanski 1991).

4.4.2.1 Single populations

4.4.2.1.1 Low population density: Allee effects. Individuals may be spread over such a large area, in comparison with their natural movement range, that their opportunities for interaction, including mating, are limited (Gilpin and Soulé 1986; Lande 1987; Dobson and Lyles 1989). This will directly affect population growth rate, which may drop below unity (death rate becoming greater than birth rate) when population density declines below a threshold value. Lowered population growth rate with decreasing density is called an Allee effect (Allee *et al.* 1949). A well-documented extinction of an isolated population in which an Allee effect was involved is the disappearance of the middle-spotted woodpecker *Dendrocopos medius* from Sweden in 1982 (Petersson 1985). Extinction induced by low population density is a particularly worrying threat for species with highly evolved sociality.

4.4.2.1.2 Demographic stochasticity. Changes in population size due to births and deaths necessarily involve chance variation (stochasticity), because individual development and physiology involve randomness, such as the sex of the offspring and the development of cancer. Hence there is a finite probability that all individuals in a population happen to die in the same unit of time (Caswell 1989). This probability (of population extinction) mainly depends on the current population size (small populations are most vulnerable), mean survival rate, and the variance in the survival rate among individuals (Goodman 1987; Mode and Jacobson 1987). Not much is known about the consequences of genotypic and phenotypic variation among individuals to the susceptibility of population extinction (Lande and Barrowclough 1987). Such variation may amplify demographic stochasticity (Bengtsson 1991) but does not do so necessarily, for instance, if phenotype \times environment interaction is important (Stearns 1992).

Though demographic stochasticity necessarily poses a significant threat to the survival of very small populations (those consisting of some tens of individuals or less), larger populations are less affected because the expected time to extinction under demographic stochasticity increases roughly exponentially with the equilibrium population size

(assuming that the population is capable of recovering from perturbations to small size; Lande 1993). In large populations, demographic stochasticity is masked by environmental fluctuations as is discussed below. In models of both demographic and environmental stochasticity, extinction times tend to be roughly exponentially distributed (Strebel 1987; Gabriel and Burger 1992), which means that many populations may be expected to go extinct quickly while a few populations may last for a long time. A corollary of this result is that the average extinction time is not a very informative statistic, as most populations would go extinct faster than the average population.

4.4.2.1.3 *Environmental stochasticity.* Probabilities of birth and death in natural populations are typically affected by environmental factors with more or less correlated effects on many individuals. Such correlated stochasticity, or environmental stochasticity, will reduce the variance in the vital rates among individuals, which has the same effect as reducing population size and is hence harmful for survival. In the extreme case of complete catastrophe, the correlation is complete: if one individual dies, all others die as well. Large population size is then no guarantee of survival.

Environmental stochasticity is reflected in temporally fluctuating growth rates of populations. Long-term growth rates in variable environments (Caswell 1989; Tuljapurkar 1990) and the consequent risk of extinction (Leigh 1981; Goodman 1987; Lande and Orzack 1988; Lande 1993; Foley 1994; Mangel and Tier 1994a) are difficult to calculate analytically. None the less, it is clear that increasing variance of the growth rate increases the risk of extinction. Extinction risk is also increased by low average growth rate, low current population size, and low equilibrium population size (Lande 1993; Foley 1994). In particular cases, sufficiently realistic models and useful

predictions may be developed with numerical methods (Lande and Orzack 1988; Legendre *et al.* 1993; Mangel and Tier 1994a, b).

Of particular importance to the survival of species in temporally varying environments is the structure of the variability, as characterized by, for example, the autocorrelation function. Species have evolved different life histories depending on the type of environmental variation encountered in the past (Kaplan and Cooper 1984; Orzack and Tuljapurkar 1989). When predictability is weak, risk-spreading strategies are expected to evolve, whereas when predictability is high, life histories geared towards maximization of short-term fitness are expected. A particular threat to species survival is a change in the pattern of variability, which may render a particular life history inappropriate in the changed environment (see below). Theoretical and empirical studies on these topics are badly needed.

4.4.2.1.4 *Genetic factors in extinction.* Two widely discussed genetic factors in extinction are elevated risk of extinction due to inbreeding depression and loss of evolutionary adaptability to novel environments due to reduced genetic variation in small populations (Lande 1988a). These genetic factors are discussed at length in Chapter 4.2: here we summarize only the key points.

If a previously large population is suddenly reduced to a small size, individuals are forced to mate with close relatives and often experience reduced viability and fecundity, known as inbreeding depression (Lande 1988a). The mechanisms of inbreeding depression are not known for most species (Thornhill 1993), but in *Drosophila* about half of inbreeding depression is due to increased homozygosity of recessive deleterious mutations at about 5000 loci: the rest is caused by numerous slightly recessive and detrimental mutations (Lande 1988a). Inbreeding depression has been well documented for domestic and

Table 4.4-3: Extinctions of rare butterflies on nature reserves in Britain between 1960 and 1982 (modified from Warren 1992).

Species	Total number of populations in Britain	Number of populations on reserves	Percentage of populations on reserves that went extinct, 1960–81
<i>Lycaena dispar</i>	1	1	100%
<i>Maculinea arion</i>	4	4	100%
<i>Carterocephalus palaemon</i>	16	4	100%
<i>Melitaea cinxia</i>	18	7	0%
<i>Melitaea athalia</i>	29	7	29%
<i>Satyrrium pruni</i>	30	11	0%
<i>Hesperia comma</i>	52	33 ¹	27%
<i>Lysandra bellargus</i>	c. 75	19	21%

1. Nine populations on reserves went extinct but four new reserves were colonized during the same time period.

laboratory organisms and zoo populations (Lerner 1954; Falconer 1981; Ralls *et al.* 1986), but there is very limited information for natural populations (Shields 1993).

The rate of loss of genetic variation due to genetic drift (Chapter 4.2) increases with decreasing population size, N , which in this context should be understood as the 'effective population size' (an ideal population of size N with random union of gametes in reproduction). Effective population size is generally much smaller than the actual population size, often only 10–50% of the censused number of individuals. In the absence of forces maintaining genetic variation (e.g. mutation, migration, selection favouring heterozygotes), heterozygosity is expected to drop to 37% of its initial value in $2N$ generations. Heterozygosity is lost even more rapidly if mating occurs non-randomly, among close relatives.

4.4.2.1.5 Summary: the critical role of population size. The central message from practically all theoretical studies on extinction is that the risk of extinction increases, and hence the expected population lifetime decreases, with decreasing population size. Empirical investigations have found ample support for this prediction (Smith 1974; Terborgh and Winter 1980; Williamson 1981; Hanski 1986; Hanski and Thomas 1994; Diamond 1984; Schoener and Spiller 1987; van Dorp and Opdam 1987; Bengtsson 1988), though the actual mechanism of extinction has remained generally unknown. Demographic stochasticity poses a real threat to survival only when population size is very small, say fewer than 50 individuals (see 4.4.4.3). Inbreeding depression is likely to be important only under special circumstances, when a previously large population is suddenly reduced to a very small size (which may happen in the colonization of a previously empty locality). Environmental stochasticity, which leads to temporal fluctuation in birth and death rates, emerges as the main mechanism of extinction. Under environmental stochasticity, extinction probability decreases with increasing population size, but if the level of stochasticity is high, in the sense of much variation in the growth rate in comparison with the average growth rate, even large populations may have a relatively short expected lifetime.

The expected population size depends critically on the availability of essential resources and on the extent of suitable habitat (Boecklen and Simberloff 1986). The negative relationship between extinction probability and the size of the habitat fragment, which may be an island or a nature reserve, is well established (Diamond 1984). Factors other than resource limitation may affect average population size, for instance predation, disease and social interactions, which thereby affect extinction risk. The type of density dependence in population regulation also has relevance to the question of population extinction. Scramble competition and density dependence acting with a time delay may amplify population fluctuations (May 1976) and thereby increase the risk of extinction.

4.4.2.2 Metapopulations: assemblages of local populations Population biology has traditionally emphasized factors that pose a threat to the survival of single populations. The practice in conservation biology is much affected by this tradition, reflected for instance in the emphasis on the management of isolated nature reserves (Table 4.4-3). But many species have survived even if there are no large enough local populations which could be expected to persist for a long time, and species have survived in continuously changing landscapes. Species living in successional habitats provide clear-cut examples (Thomas 1995). In any one place, the right kind of habitat is present only for a limited period of time and local extinctions are inevitable, but a species may survive regionally if it is able to establish new local populations elsewhere, where the right kind of habitat has appeared. An assemblage of such extinction-prone local populations, connected to each other by migrating individuals, is a form of metapopulation (Levins 1969, 1970; Hanski 1991; see 4.3.1). Box 4.4-1 describes an example of an endangered species of butterfly persisting as a metapopulation in a naturally fragmented landscape.

Metapopulation persistence hinges on the processes that affect the rates of local extinction and the establishment of new populations. A necessary condition for metapopulation persistence is that the rate of establishment of new populations exceeds the rate of extinctions when the metapopulation is small, that is, when only a small fraction of the suitable habitat (patches) is occupied (this condition is analogous to the requirement that the expected birth rate must exceed the expected death rate for a local population to survive). Mechanisms of local extinction have been discussed above. Generally, extinction risk increases with decreasing population size and hence, typically, with decreasing size of the respective habitat patch (Hanski 1994b). A new element introduced by the metapopulation concept is the establishment of new populations, which has two necessary requirements: there must exist habitat patches in which a new population can be established, and there must be sufficient migration of individuals from the existing populations to the currently empty patches. Therefore, if a species functions as a classical metapopulation with high risk of local extinction, long-term persistence of the metapopulation depends not only on the currently occupied habitat patches (existing populations) but also on the presence, in sufficient numbers and at not-too-great distances, of unoccupied but suitable habitat. The emphasis on migration in metapopulation theories enlarges the biological traits that are significant in the context of population extinction.

Not all species are structured as classical metapopulations even in fragmented landscapes. In some cases the persistence of the metapopulation depends on some large core population(s) with a small risk of extinction, and which serves as a permanent source of

Box 4.4-1: Metapopulation persistence of an endangered butterfly in a fragmented landscape.

The Glanville fritillary *Melitaea cinxia* has become extinct or severely declined in many parts of Europe during the past few decades (Hanski and Kuussaari 1995). In Finland, the butterfly survives only on the *ül*and islands, within an area of 50 km × 70 km, in a network of 1502 suitable habitat patches (see map) in dry meadows with the larval host plants *Plantago lanceolata* and *Veronica spicata*. In 1993, a local population was found on 536 meadows (black dots on map; grey dots represent suitable but empty meadows). Hanski *et al.* (1995) conclude that the long-term persistence of this butterfly on *ül*and is based on metapopulation-level dynamics, i.e. a balance between stochastic local extinctions and recolonizations, because this metapopulation satisfies the following four conditions:

Condition 1. The species has a metapopulation structure: meadows are occupied by well-defined local populations, with >80% of butterflies staying on the natal meadow (Hanski *et al.* 1994).

Condition 2. The largest local population was <1000 individuals in 1993. Many studies on this and related butterflies (Table 4.4-3) have shown that such small populations are not safe from extinction on the time scale of tens of years.

Condition 3. The nearest-neighbour distance between meadows is 240 m (maximum 3870 m), whereas the mean, median and maximum distances moved by dispersing butterflies were 590 m, 330 m and 3050 m. Therefore, the meadows are not too isolated to prevent recolonization.

Condition 4. Local dynamics are not well synchronized, for reasons discussed in Hanski *et al.* (1995), which makes simultaneous extinction of all local populations unlikely.

Effect of patch area			Effect of patch density		
Area (ha)	Occupancy		Patches per 4 km ²	Occupancy	
	<i>n</i>	<i>P</i>		<i>n</i>	<i>P</i>
<0.01	23	0.24	1	61	0.21
0.01–0.1	138	0.24	2–3	70	0.32
0.10–1.0	88	0.40	4–7	58	0.25
>1.0	6	0.56	>7	66	0.41

The table illustrates how the fraction of suitable meadows occupied by the butterfly at one point in time decreases with decreasing average area and increasing isolation of the meadows. For this analysis, the geographic range of the species was divided into 2 km × 2 km squares, and the fraction of occupied meadows in each square was scored (= occupancy, *P*). The area in the table gives the average area of meadows in the square. For details see Hanski *et al.* (1995).

immigrants to peripheral and smaller habitat fragments, where extinctions may be common (mainland–island metapopulations; Hanski 1991; Harrison 1991, 1994). In this case the conservation of the core population is critical. In other metapopulations some local populations serve as net producers of immigrants because of high population growth rate, perhaps due to superior habitat quality, while population growth rate in other populations may be significantly enhanced by immigration from these source populations (source–sink metapopulations; Pulliam 1988). Finally, an apparent metapopulation structure is no guarantee of long-term survival: the metapopulation may occur in a recently fragmented landscape where no balance between extinctions and colonizations has been achieved, and the entire metapopulation may be slowly declining to extinction (non-equilibrium metapopulations; Hanski 1994c).

Assuming that the landscape structure and the biology of the species would allow, in principle, long-term persistence of the metapopulation, its survival is threatened by two forms of metapopulation-level stochasticity, analogous to demographic and environmental stochasticities in the dynamics of local populations (Hanski 1991).

4.4.2.2.1 Colonization–extinction stochasticity. A metapopulation may go extinct, by chance, if it consists of a small number of local populations with a high risk of extinction: all local populations may go extinct at the same time. Colonization–extinction stochasticity poses a real threat to metapopulations living in networks consisting of only a few habitat patches. Thomas and Hanski (1991) suggest, based on both theoretical considerations and empirical data on butterflies, that a minimum of 10 to 15 well-connected habitat patches is required for long-term persistence when all patches are small and hence local populations have a high risk of extinction.

4.4.2.2.2 Regional stochasticity. Environmental variability, for instance weather effects, often affect the dynamics in and therefore the extinction and colonization probabilities of several local populations in a metapopulation. Such spatially correlated environmental stochasticity is called regional stochasticity. Typically, the strength of regional stochasticity decreases with increasing distance between local populations. Hanski and Woiwod (1993) demonstrated that the level of climate-induced synchrony in the dynamics of insect populations declined with distance in the UK, though a low level of synchrony remained up to almost 1000 km. Regional stochasticity increases the risk of simultaneous local extinctions and hence the risk of extinction of the entire metapopulation (Quinn and Hastings 1987; Gilpin, 1988 1990; Hanski 1989; Harrison and Quinn 1989).

4.4.3 Causes of extinction

In the above discussion of the mechanisms of extinction, we assumed no systematic environmental change, that is,

no change in the mean nor in the variance of the relevant biotic or abiotic parameters. This is the situation which biologists interested in the process of population extinction have traditionally assumed (Caughley 1994). In the real world, most environments change, and often in a complex manner. There is little doubt that the current escalation of the extinction rate is primarily caused by environmental changes, which may affect all the key parameters of the risk of extinction – current population size, equilibrium population size ('environmental carrying capacity'), population density, the mean and the variance of the population growth rate, the genetic structure of populations, and the size, number and distances apart of habitat patches and local populations in a metapopulation. Below, we discuss five kinds of environmental change and how they relate to the above-described mechanisms of extinction.

4.4.3.1 Loss of habitat

The most important reason for population extinctions, especially on small spatial scales, is habitat destruction (see Section 11). For instance, Temple (1986) has estimated that the following factors have significantly increased the risk of extinction of endangered bird species: habitat loss has affected 82% of the species, collecting has affected 44% of the species, interactions with introduced other organisms (predators, competitors) have affected 45% of the species, and 12% of the endangered bird species have suffered from other causes (many have been affected by several factors). At larger spatial scales, a metapopulation may go extinct when the density of habitat patches decreases below a critical threshold level (Hanski 1991; Nee and May 1992), even if some suitable habitat would still remain.

There is no 'safe' non-trivial level of habitat loss which would not increase the risk of extinction of some species. The reason for this bleak conclusion is that different species have different ecologies and individualistic patterns of spatial distribution; there are hardly any areas that would not be significant for the survival of some species, even if some areas have significantly more rare and endangered species than other areas ('hotspots'; Myers 1988). Prendergast *et al.* (1993) reached a similar conclusion from a comparison of distributional patterns in endangered animals and plants in the UK: no network of carefully selected reserves would suffice to protect all the species. In recent years, extinctions caused by habitat loss have been discussed most frequently in the case of tropical forests (Chapter 4.5), but habitat loss poses a severe threat in all biomes.

The risks associated with habitat loss are easier to assess when considering particular species, but the loss of biodiversity cannot be minimized just by a careful consideration of single species. Regardless of the context in which the consequences of habitat loss are assessed, loss of

natural habitats is the key ultimate cause of the present high rate of extinctions.

4.4.3.2 *Change in habitat quality*

Change in habitat quality, a less extreme environmental change than complete loss of habitat, may affect the mean and the variance of population growth rate as well as the equilibrium population size. Recent studies have emphasized likely changes in habitat quality due to climate change (Kareiva *et al.* 1993). A fundamental question in this context is whether species have enough time to migrate to new areas where conditions remain favourable, or have enough time to evolve locally (Lynch and Lande 1993). The rate of environmental change may well be faster than can be tracked by evolution in a local population, and some predictions about critical rates of environmental change beyond which extinction is inevitable have been made based on quantitative genetics theory. A different question is whether populations will respond by evolving or by changing habitat or geographic range.

A huge amount of empirical knowledge exists about the habitat requirements of a vast number of species, including most vertebrate species and many rare and endangered species. This knowledge, much of which remains as unwritten, personal experience of field biologists, is one of the most relevant sources of information for conservation biology (the challenge for conservation biologists is to collect, classify and maintain this information for easy access by all potential users; see Section 9). For many species, the consequences of even subtle changes in habitat quality can be confidently predicted on the basis of the existing knowledge about the species' requirements.

It is worth emphasizing in this context how superficial observations may lead to misleading conclusions. For instance, an increasing trend in population size over a short period of time is not a sufficient reason to expect low risk of extinction, as a small population may increase temporarily, by chance, even if its expected growth rate is below unity. In the same vein, the mere observation that a species is present in some particular habitat, even in large numbers, does not allow us to conclude that such populations are viable. There are examples in which the presence of a species in some (sink) habitats can only be maintained by immigration from other (source) habitats, where population growth is balanced by emigration (Pulliam 1988, 1994; Pulliam and Danielson 1991; Howe *et al.* 1991; Davis and Howe 1992). The possibility of such source–sink metapopulation dynamics should be taken into account while assessing population dynamic consequences of habitat loss and habitat change.

4.4.3.3 *Habitat fragmentation*

Habitat fragmentation may convert a previously more continuous population structure to a metapopulation

structure, with all or most local populations becoming so small that they have a substantial risk of extinction. Long-term persistence at the level of local populations becomes less likely, but metapopulation persistence still remains a possibility. One poorly understood but critical question is that of under which conditions a species that has evolved in a more continuous habitat will survive, or evolve to survive, in the more fragmented environment (see also discussion in Section 11.2.2.3).

A crucial factor in metapopulation survival is migration (dispersal) among habitat patches. Migration is often thought to have evolved to 'solve' an ecological problem, habitat instability, or a genetic problem, inbreeding depression (Dobson and Jones 1985; MacDonald and Smith 1990; Lidicker and Stenseth 1992). Strictly speaking, migration is expected to evolve whenever it increases individual fitness (Hamilton and May 1977). Of particular significance is the observation that individual selection does not necessarily lead to a migration rate that would maximize metapopulation persistence (Comins *et al.* 1980). High migration rate selected by group selection may occur in species that have evolved in patchy environments (Wilson 1980), but it is an open question whether such group selection will become a significant factor in environments fragmented by humans. The pessimistic but probably realistic viewpoint is that in recently and quickly fragmented landscapes, individual selection operating in local populations decreases migration rate further and thereby makes long-term persistence at the metapopulation level even less likely. Dempster (1991) describes some putative examples from endangered British butterflies.

Habitat fragmentation may increase the risk of extinction in many surprising ways. With decreasing fragment size relatively more of the habitat becomes affected by the edge of the habitat fragment. For instance, generalist predators invading the fragment from outside often impose an increasingly heavy mortality with decreasing fragment size on habitat specialist prey species (Wilcove 1985; Andrén and Angelstam 1988). Fine-scale habitat fragmentation may disrupt the usual foraging and breeding behaviour of species that have evolved to live in more continuous habitat, and thereby the population growth rate may become lowered (Rolstad 1991).

4.4.3.4 *Persecution and exploitation of populations*

Risk of extinction due to persecution and exploitation of populations has been, and continues to be, a special threat to some species, especially large vertebrates. Human hunters may have caused the extinction of large mammoths and other large-bodied Pleistocene mammals 10 000–20 000 years ago (Martin and Klein 1984). Large vertebrates generally attract the greatest public attention and the most detailed scientific scrutiny. Much of the theoretical study of the mechanisms of extinction (see 4.4.2) is also most

applicable to such species, and an extensive body of literature has been written on the subject of controlled exploitation of their natural populations to obtain a (maximum) sustainable yield (Getz and Haight 1989) and to avoid population extinction.

It is often assumed that large animals need large reserves because of their low population density. Large animals typically have lower densities than small ones (Peters 1983), though in many cases the observed low density is partly attributable to persecution. But equally importantly, many large species would survive in somewhat modified environments if they were not persecuted. For instance, in Finland most large-bodied birds and mammals, including both herbivorous and predatory species, have become more abundant in recent decades in a range of managed landscapes, apparently because they are no longer persecuted as widely as they used to be. Large reserves are needed if persecution outside the reserves cannot be eliminated. A point worth making in this connection, though not related to persecution, is that large reserves may often be needed most for the protection of the vast range of small-bodied specialist species which live in (networks of) microhabitats found only in large intact stretches of habitat (Hanski and Hammond 1995).

4.4.3.5 Change in the biotic environment

Another cause of extinctions is interaction with alien species, spread naturally or, more frequently, transported by humans to new environments. The spread of non-indigenous species is second only to habitat destruction in harming native communities (Simberloff 1995) (see also discussion in Section 11.2.2.4). The threats posed by non-indigenous species are especially grave on oceanic islands with small areas and specialized species (Atkinson 1989), though large area itself is no guarantee of survival: the red fox, an introduced generalist predator in Australia, appears to be the main cause of the extinction of several small marsupials (Dickman *et al.* 1993). Humans have also enhanced the spread of diseases and parasites, which may be responsible for more extinctions than is commonly believed (McCallum and Dobson 1995).

Human-induced extinctions of species on oceanic islands have occurred on a much larger scale than is generally recognized. Table 4.4-1 indicates that roughly 1% of bird species have gone extinct in historic times, most of them on oceanic islands. But this figure is a gross underestimate of the true number of island extinctions in recent times. Olson (1989) estimates that as many as one-quarter of the bird species that existed a few thousand years ago have already perished on islands under human influence. For instance, only three species of flightless rails remain, while hundreds most probably occurred on the thousands of islands in the Pacific in the past 2000 years (Olson 1989). We are rightly concerned about the imminent wave of mass extinctions in

tropical forests, but on oceanic islands a wave of mass extinctions has just occurred.

Hybridization with non-indigenous species and other forms of genetic introgression threaten large numbers of species in certain groups of birds, for instance ducks, and also mammals and fishes (Simberloff 1995).

4.4.3.6 Summary

In some cases a specific factor is known to have caused population decline, but in other cases no single cause can be identified. An example of the latter is the severe decline in the distribution and abundance of the European mink *Mustela lutreola*, once widely distributed in Europe, now surviving in less than a fifth of its original range with an estimated total population of 30 000 (Maran and Henttonen 1995). In this case, several factors are known to have contributed to the demise of the species in different places at different times: loss and fragmentation of habitat, loss of a key food source (the crayfish *Astacus astacus*), exploitation, competition with the introduced American mink *Mustela vison*, and hybridization with the European polecat *Mustela putorius* (Maran and Henttonen 1995). Compared with congeneric species, the European mink is an ecological specialist, and though widely distributed in Europe in the past, its occurrence may always have been relatively precarious. The European mink appears to be poorly adapted to cope with any kind of environmental change. In this respect it may exemplify many other specialized endangered species.

4.4.4 Predicting extinction rates

Predicting the expected lifetime of a population is a tremendously difficult and complex task as discussed in 4.4.1. Extinctions of particular species in particular environments can be predicted reliably only in those cases where there is an obvious environmental cause of extinction, be it habitat destruction, persecution or something else. In the absence of systematic environmental change, populations still face a risk of extinction. This is typically greater in the case of smaller populations, but in this case only statistical predictions of extinction are possible.

4.4.4.1 Single populations

An important first point to appreciate is that because of variation in population growth rates, a short record of increasing population size, especially in small populations, should not be accepted as sufficient evidence for long-term persistence (Lande and Orzack 1988). Secondly, simple models of population dynamics, with constant parameters and possibly no population regulation (density dependence), are not adequate for quantitative prediction of long-term dynamics, but such models may give valuable insight into the sensitivity of population growth rate and hence extinction proneness to modifications in age-specific fecundity and survival, age at maturity, etc. (Caswell 1978,

1989; Lande 1988a; Groenendael *et al.* 1988; Houllier and Lebreton 1986; Lebreton and Clobert 1991). Such information can be useful in indicating which management options are most likely to affect the risk of extinction (Pinero *et al.* 1984; Crouse *et al.* 1987; Lande 1988b; Menges 1990; Wootton and Bell 1992). These models are not yet used as widely as they should be in conservation biology. There is a demand for microcomputer programs in which such approaches have been implemented (Ferson and Akcakaya 1990; Shaffer 1990; Boyce 1992; Legendre *et al.* 1993).

Thirdly, classical models of population extinction are focused on demographic stochasticity (MacArthur and Wilson 1967). These models are of very limited use, because the impact of environmental stochasticity is overwhelmingly important in practically all natural populations. Furthermore, most models of demographic stochasticity ignore within-population heterogeneity, such as age structure, and the spatial extent of the population (Allee effect). Extinction models incorporating environmental stochasticity are potentially more useful, and several such models have been developed in recent years (Leigh 1981; Goodman 1987; Lande 1993; Foley 1994; Mangel and Tier 1994a, b). It is unfortunate that testing these models is difficult with the kind of data that are available and hence has rarely been attempted (Belovsky 1987; Foley 1994). A novel approach to estimating extinction rates from patterns of habitat patch occupancy in a metapopulation has been described by Hanski (1994a, b).

Fourthly, a particular difficulty in the prediction of extinction risk under environmental stochasticity is that the level of stochasticity assumed in the model is typically estimated from the past record of stochasticity (as reflected in the variability of population growth), over a relatively short period of time. Extinctions may often be triggered by novel sources of stochasticity, which could not have been anticipated from the past record. Mangel and Tier (1994b) make this point by observing that extinctions may often be caused by catastrophes – ‘unexpected’ environmental disturbances with a large impact on the population. An extreme possibility is that many of the extinctions in the past are due to catastrophes of various magnitude caused by meteorite impact (Raup 1991a). Mangel and Tier (1994a, b) have developed numerical methods to calculate extinction time from the knowledge of how birth and death rates depend on population size.

Finally, in a large assemblage of similar populations, extinction times are expected to be exponentially distributed, as we have already explained, which means that many populations go extinct very quickly while a few may last for a very long time. In this situation the average extinction time is a misleading statistic.

4.4.4.2 Metapopulations

Metapopulation models make predictions about metapopulation survival and expected lifetime in

fragmented landscapes. This may be the most relevant class of model for many environments extensively modified by humans. They may be used to draw recommendations about how landscapes should be modified to enhance metapopulation persistence (Hanski 1994a).

General metapopulation models indicate the conditions that must be met for long-term metapopulation persistence. Though not helpful in generating predictions for particular metapopulations, the qualitative conclusions are useful in directing attention to the factors that are likely to affect critically the survival of many species in fragmented landscapes. First, habitat fragments should be sufficiently large and located sufficiently close to each other to generate enough recolonizations to compensate for local extinctions. Second, the level of spatial correlation in environmental stochasticity (regional stochasticity) should be minimized. There is little that we can do with climate and weather conditions, which are the main cause of environmental stochasticity and are typically correlated over large spatial scales (for the effects on insect populations, see Hanski and Woiwod 1993). Often, however, the effects of weather are modified by local habitat quality. For instance, host plants for an insect species growing in different microhabitats may be more or less vulnerable to drought (Weiss *et al.* 1993). An obvious recommendation stemming from the general need to minimize regional stochasticity is then the following: in the case of multiple reserves, it may be better to include sites with variation in habitat quality, or to manage sites so that they retain a range of habitat qualities, rather than to aim at some single ‘best’ quality, which may be best in most years but fail badly under unusual circumstances. An additional advantage of having sites varying in quality is the possibility of increased genetic variation for stress-resistant traits in the metapopulation (Hoffmann and Parsons 1991).

Quantitative predictions about the risk of metapopulation extinction have to be based on models that incorporate the spatial locations of local populations and which allow explicit modelling of migration. Such models range in complexity from relatively simple incidence function models (Hanski 1994a, b) to complex simulation models (McKelvey *et al.* 1993; Hanski and Thomas 1994; Lahaye *et al.* 1994; Lamberson *et al.* 1994), possibly linked to Geographic Information Systems-orientated landscape descriptions (Akcakaya 1993). An ambitious example of the latter is the modelling of the northern spotted owl in North America (McKelvey *et al.* 1993). Model complexity is not necessarily a great virtue, however, and often simpler models are more practical in particular cases. In conservation, the main question is often to evaluate alternative scenarios of landscape change rather than to aim at accurate long-term predictions.

Regardless of the modelling approach adopted, one general difficulty remains. It is unlikely that the fragmented

environment in which the metapopulation now occurs will remain unchanged for long. Metapopulation dynamics necessarily occur on a relatively long time scale, and often it is doubtful whether a stochastic steady state between extinctions and colonizations will ever be reached. It is probable that a large number of threatened species occur in fragmented landscapes that are already inadequate for their long-term survival: the species still exist because they have not yet had time to go extinct (Hanski 1994c). How many such 'relict' or non-equilibrium metapopulations our fragmented landscapes presently harbour is an urgent question for conservation biologists.

4.4.4.3 *Population viability analysis*

The ultimate aim is to develop a procedure that will predict the expected lifetime of a population taking into account all the relevant mechanisms and causes of extinction, instead of focusing on some particular mechanism or cause. Such a procedure is known as Population Viability Analysis, PVA (Shaffer 1981, 1990; Gilpin and Soulé 1986; Soulé 1987; Boyce 1992). A general description of what constitutes a PVA is not possible, because any critical analysis involves an in-depth study of the biology of the focal species (or collection of relevant literature data) and is hence species-specific. Some 35 PVAs had been attempted by 1992 (Boyce 1992), though most of them have never been properly documented and published. The best known PVAs include those on the grizzly bear (Shaffer 1983) and the northern spotted owl (Marcot and Holthausen 1987; Lande 1988b) in North America.

An important element in Population Viability Analysis is the concept of Minimum Viable Population, MVP. Populations that are smaller than MVP are considered to be in imminent risk of extinction, hence the first priority in conservation must be to increase the population size and keep it above the MVP. Three values of MVP for three threats to survival are often mentioned in the conservation biological literature: MVP to avoid extinction due to demographic stochasticity (roughly 20 individuals; MacArthur and Wilson 1967); MVP to avoid inbreeding depression (roughly 50 individuals; Franklin 1980); and MVP to allow evolutionary change (roughly 500 individuals; Franklin 1980). The first value is based on simple models and is most probably an underestimate. To take into account individual variation in age, sex and other such factors, the demographic stochasticity MVP should be increased to at least 50–100 individuals (Ebenhard 1991). The latter two values refer to ideal populations in the population genetics sense. To take into account the difference between the actual and genetic effective population sizes, these MVPs should be increased to roughly 500 and 5000 individuals, respectively (Nunney and Campbell 1993).

These specific values of MVP and their justifications are discussed in the technical literature (Lande 1976, 1988a;

Franklin 1980; Lande and Barrowclough 1987; Boyce 1992). An important conclusion to emerge is that no universally applicable MVP sizes can be defended, and no conservation decisions should be based solely on such 'magic' numbers. None the less, as a general aim for the short-term conservation of any species, several hundreds of individuals should be maintained (Thomas 1990), as a minimum, and preferably in several localities (independent populations). More specific recommendations and the long-term conservation strategy must be based on knowledge of the biology of the species. Furthermore, if unusual events (catastrophes) are generally critical in population extinction (Raup 1991a; Mangel and Tier 1994b), the Minimum Viable Population concept has relatively little utility, and the only general conclusion that can be drawn safely is that smaller populations tend to have a shorter expected time to extinction than large ones.

4.4.5 *Summary*

It is obvious that the rate of extinction today is hundreds, if not thousands, of times higher than the natural background rate that prevailed before the beginning of rapid human population growth, a few thousand years ago. An examination of the mechanisms and causes of extinction reveals many issues and factors that are relevant to the study of extinctions. The process of extinction is examined above at two different scales: at the scale of single populations and at the scale of metapopulations (assemblages of local populations connected by migration). Several factors are particularly crucial to the survival or extinction of single populations: Allee effects (negative population growth in low density), demographic stochasticity due to randomness in births and deaths, environmental stochasticity due to weather effects and other such external randomness, and genetic factors. Theoretical studies dealing with all of these factors have uniformly concluded that the risk of population extinction increases as its size decreases. This conclusion is the most vital point of the summary above. Almost as important is the size of the habitat fragment in which the population is allowed to live. All of the factors important to single populations apply to metapopulations. However, the metapopulation concept brings several more ideas into play. The rate of migration into available habitat is important for species survival, as is the rate of formation of new habitats suitable for colonization. Colonization–extinction stochasticity and regional stochasticity (spatially correlated environmental stochasticity) are processes that are important to the dynamics of metapopulations.

Among the causes of extinction, environmental change is the most important, especially when it involves loss of habitat. In order to determine whether or not populations and metapopulations are truly in danger, models have been used to predict their fate. Population Viability Analysis

promises to predict for how long particular populations are expected to survive, taking into account all the known mechanisms of extinction. These models are valuable because they go one step further than the simple examination of the mechanisms and causes of extinction, and can be applied to specific situations and species. However, conservation strategies formulated to avoid extinction must not only include models that take into account the many factors that contribute to the decline of populations and species, but must also incorporate specific biological knowledge of the species in question.

4.5 Dynamics of biodiversity at the community and ecosystem level

4.5.1 Introduction

The main objective of this chapter is to emphasize the community and ecosystem context in which biodiversity originates, is maintained, and is lost. It will serve as an introduction to the processes that will be further developed in Sections 5 and 6.

The biodiversity present in any biotope is not a fixed attribute of that biotope but a dynamic attribute of communities and ecosystems. It is constantly changing, on both relatively short ecological time-scales and long evolutionary time-scales, and at any point in time it results from the past and present selective pressures exerted on the various organisms by the other components of the ecosystem, such as physicochemical factors, food, competitors, predators, parasites, diseases, mutualists, and the spatial and temporal variability of the environment. Thus these ecological factors play a central role in shaping local genetic and species diversity within populations, communities and ecosystems. The dynamics of biodiversity – the changes of biodiversity in time and space and the causes of such changes – cannot be understood without due consideration of the dynamics and organization of communities and ecosystems. A community- and ecosystem-centred viewpoint is indispensable in any management policy for natural or semi-natural habitats, whether nature reserves, national parks, forests or arable land.

Recently, much attention has been given to estimating the total number of existing species (e.g. May 1990, 1992; see Section 3.1.2). It is important to humankind to know the full diversity of their living companions on Earth but it is also necessary to use this framework of knowledge to investigate why there are so many species in the first place (Hutchinson 1959; MacArthur 1972; May 1973) and how their diversity is maintained. In other words, it is necessary to investigate both the species and ecosystem components of biodiversity: species exist in ecosystems and ecosystems are composed of species. Although species-level studies are still essential if one is interested in maintaining particular species (such as whales, elephants or the spotted owl) or

managing the genetic diversity of a given food crop species, it has been argued by some that, in general, the ecosystem component of biodiversity has been neglected and proposals to shift the emphasis from species to communities, ecosystems and landscapes have recently taken on a new intensity (Franklin 1993; Wiens *et al.* 1993; Barbault 1994, 1995).

The most sensible route towards understanding and predicting the dynamics of biodiversity is to develop fundamental and general ecological theory with the ultimate goal of linking diversity patterns, population dynamics, community organization and ecosystem functioning (Barbault and Hochberg 1992; Jones and Lawton 1995). Then, empirical observations and experiments to validate and test the theory become fruitful. A community ecology approach to biodiversity is especially useful because (1) it links population and conservation biology to ecological constraints; (2) it encourages integrated approaches that explicitly take into account the multifaceted nature of biodiversity dynamics, from individual organisms to ecosystems and landscapes; and (3) it links patterns and processes, by emphasizing the mechanisms that lead to the local build-up, maintenance, and erosion of biological diversity (Pimm 1991; Barbault 1992). Understanding how communities are assembled and maintained is necessary to assess the biological consequences of global change (Kareiva *et al.* 1993) and the way we can safeguard biodiversity (Western 1992). Today, conservation biologists face the same challenge as many community ecologists have faced for decades: identifying the processes and mechanisms that determine the diversity of communities and the relative abundance of species.

4.5.2 Competition and community organization

To grow, live and reproduce, every organism requires a favourable combination of abiotic environmental conditions – such as temperature, moisture, pH, salinity, current flow or soil structure, and a set of resources to provide it with energy and matter – mainly solar radiation, water and nutrients for plants, and food derived from other organisms for animals. The basic and obvious dependence of all organisms on such conditions and resources has naturally led ecologists to first seek an explanation of the composition and diversity of plant and animal communities in the local abiotic factors and resource availability. Communities were often considered and described as simple associations of species with similar requirements, and these associations did not necessarily involve any form of interaction among species in the communities.

A radically different and novel view of communities emerged from the mathematical models and experiments developed by Lotka (1925), Volterra (1926), Gause (1934) and others in the 1920s and 1930s. This theoretical and

experimental work focused on the dynamics of species interactions in simple model systems, and arrived at some strong results, in particular regarding competition between species. Competition refers to a negative mutual interaction between organisms resulting from the utilization of shared resources in limited supply. The models of Lotka, Volterra and Gause predicted that two species would not be able to coexist in the long term if they used the same resources, the more efficient competitor ultimately excluding the less efficient one. This prediction was successfully confirmed by Gause's experiments. It was later elevated to the rank of the 'competitive exclusion principle', and served as the foundation for a rich body of theory regarding competition as the major process leading to community organization and patterns. The importance of this principle was noted by many, notably Lack (1944), who pointed out that it should result in the partitioning of resources among species. As a corollary, the more the resources are partitioned, the higher the diversity of species. Hutchinson (1957, 1959) took Lack's reasoning one step further; he formalized resource utilization in terms of an ecological niche with measurable attributes in a multidimensional niche space. This formalization could now be applied to whole communities. Decisive developments of niche and competition theory were then made by MacArthur and Levins in the 1960s and early 1970s (MacArthur and Levins 1967; MacArthur 1972; May and MacArthur 1972), who formally related niche overlap and competition strength, and formulated the concept of limiting similarity. According to this, there is a maximum degree of niche overlap that can be tolerated between species for their continued coexistence.

Despite persistent controversies, niche and competition theory enjoyed a growing popularity among ecologists during the roughly 30 years that followed World War II. Innumerable studies applied its principles and concepts to the interpretation of patterns within communities. Several factors can explain its success:

- The theory provided explanations for the structure and species diversity of communities in terms of a simple lower-level process that was clearly identified and demonstrated by both mathematical models and laboratory experiments. Contrary to the views that were popular at the turn of the century, emphasizing the role of geographical and historical factors acting on broad spatial and temporal scales, this could reduce species diversity to small-scale interactions among component species. As in other sciences, this reduction power was a compelling attraction of the theory.
- Interspecific competition within communities is a simple extension of intraspecific competition within populations, both conceptually and in its mathematical formalization in models. Competition

among individuals of the same species was increasingly recognized as a necessary process in the stabilization or regulation of natural populations, hence competition was likely also to be important among individuals of different species.

- The empirical delimitation of communities by ecologists unconsciously favoured the search for competition as compared with other types of interactions such as predation and mutualism. Biologists and ecologists have the natural tendency to concentrate on particular taxonomic groups because the systematics, biology, ecology and study methods of taxonomically related species are also related. Competition is likely to be more frequent among species that use similar resources, hence also among taxonomically related species.
- Although science strives for objectivity, it can never be impervious to ambient ideology. In a society governed largely by competition relationships, it is inevitable that human beings tend to find the image of this competition in the natural world. This may in part explain why mutualism received so little attention compared with competition.
- Last but not least, competition is the only elementary interaction that results in a simple, potentially universal form of community organization. MacArthur (1972) compared the order generated by competition in communities to the formation of a crystal: competition tends to lead to a regular spacing of the species' niches, to a complementary utilization of available resources by the various surviving species. MacArthur went even further, for he showed that competition generates not only structure, but also functional properties at the community level — namely, competition results in a community that optimizes the fit between overall resource utilization and resource production (MacArthur 1970, 1972; Gatto 1990). Therefore, competition theory is able in principle to predict the number, identity and relative abundances of species in a community (MacArthur 1972; Tilman 1982).

The power, consistency and simplicity of niche and competition theory has exerted a considerable attraction on generations of ecologists. Since the theory predicts niche differentiation and resource partitioning among species at equilibrium, all forms of niche differentiation and resource partitioning have been looked for, and found, in natural communities. These forms include food partitioning according to prey size or prey type; temporal segregation during the day or the year, horizontal and vertical spatial segregation; complementarity between several niche dimensions; regular spacing of morphological characters such as body or beak size; and complementary

biogeographical distributions, but other patterns have also been interpreted in the light of the theory, such as the lower species/genus ratios (or average numbers of species per genus) on islands as compared with continents.

As is often the case, the strength of a theory turns eventually into a weakness. So many patterns in so many communities were interpreted as evidence for competition that the theory threatened to become a dogma. In the late 1970s and the 1980s, a number of scientists questioned these interpretations and submitted them to an intense statistical scrutiny. Rather than searching for patterns confirming the predictions of competition theory, they argued, one should instead try to falsify the null hypothesis that communities are random assemblages of independent species. Thus patterns have to be tested against *ad hoc* 'neutral' or 'null models' simulating communities as they would appear in the absence of interspecific competition. The first application of this type of approach dates back to Williams (1964) and Simberloff (1970), who conclusively established that the lower species/genus ratios on islands were statistical artefacts due to sampling of a smaller number of species. Simberloff and others then applied their 'null model' approach to the other patterns taken as evidence for the role of competition in communities (Strong *et al.* 1979; Connor and Simberloff 1979; Simberloff and Boecklen 1981; den Boer 1985). They almost invariably failed to detect any significant pattern and concluded that communities were likely to be random assemblages of independent species.

It soon appeared, however, that those 'null' models were very sensitive to hidden underlying assumptions, that they incorporated some competitive effects implicitly, and, accordingly, that the power of the tests was often so low that it was very difficult, indeed sometimes impossible, to reject the null hypothesis (Diamond and Gilpin 1982; Colwell and Winkler 1984; Loreau 1989b). Other, more powerful 'null' models were elaborated and successfully revealed significant patterns consistent with competition theory (Lawlor 1980; Gilpin and Diamond 1982; Schluter and Grant 1984; Schoener 1984; Loreau 1989b; Pimm and Gittleman 1990). Although some (but by no means all) community-wide patterns resisted this statistical scrutiny, the 'null model' controversy was beneficial in that it contributed greatly to relativize the role of competition in community organization. First, it forced community ecologists to view competition as one explanatory hypothesis among others. Sometimes even significant niche differences at one trophic level may in part reflect structure at the lower trophic level (Loreau 1994); only in rare cases have variations in resource availability been explicitly factored out (Schluter and Grant 1984). Second, significant patterns were usually detected only among a few closely related or dominant species and tended to vanish when large and heterogeneous assemblages of species were

considered (Gilpin and Diamond 1982; Loreau 1989b). Therefore, competition is unlikely to be the sole or major force structuring large communities.

One limitation inherent in the analysis of patterns is that it does not directly provide insight into the processes generating the patterns; the influence of a process such as competition is inferred indirectly from its predicted long-term consequences. Another approach used to test competition theory more directly has been field experimental manipulations. Field experiments, notably on interspecific competition, developed dramatically during the 1970s and 1980s. Although technically demanding, time-consuming and difficult to interpret, they often offer unique opportunities to test theories and processes under the conditions of the real, heterogeneous and fluctuating world. Competition between species has usually been tested by removing or adding populations and monitoring the responses of the other species. Schoener (1983) reviewed 164 field experimental studies on interspecific competition, and found that 90% of them had demonstrated the existence of interspecific competition. In a similar but more selective review of 72 studies dealing with a total of 527 field experiments, Connell (1983) found that interspecific competition was demonstrated in most of the studies and 43% of the experiments. In a meta-analysis of field competition experiments, Gurevitch *et al.* (1992) found that competition had a large effect overall, but with a great deal of variability among organisms.

Despite some discrepancies, these reviews do suggest that current interspecific competition is widespread. Its high percentage occurrence in the studies reviewed should not, however, be taken as representing its actual prevalence in natural communities. It is very likely that the species used in most experiments were chosen precisely because they were expected to compete, and positive results demonstrating competition were more readily reported and accepted for publication than were negative results failing to demonstrate significant effects. As Begon *et al.* (1990) put it, 'Judging the prevalence of competition from such studies is rather like judging the prevalence of debauched clergymen from the "gutter press"'. In addition, some groups of organisms are much less likely to compete than others (Gurevitch *et al.* 1992). Strong *et al.* (1984) reviewed studies on interspecific competition among phytophagous insects, and found that this was demonstrated in 41% of the studies, but only in a very small proportion of the possible pair-wise interactions. Interspecific competition may be especially rare in the group of phytophagous insects, as other data suggest (Lawton 1984). Lastly, while field experiments showed that competition is a significant force in many communities, they often did not show complete competitive exclusion of one species by another and, as far as is known, never showed regulation of species diversity by competition.

Therefore, once analysed critically, the recent evidence from both the 'null model' and field experimental approaches suggests similar tentative conclusions on the role of competition in community organization:

1. Interspecific competition plays some role in natural communities in agreement with the theory. It is relatively widespread, and it does seem to constrain local species diversity by limiting niche overlap among related species.
2. However, it is highly unlikely to explain the full structure and species diversity of communities, especially of large and heterogeneous communities. Even when it is important, it may significantly affect only a small proportion of the species interactions. It should mainly affect species with closely related niches, and dominant species reaching high enough densities (Hanski 1982; Loreau 1992, 1994).
3. Interspecific competition also varies greatly in importance from community to community. It tends to be more important in communities of large-bodied, territorial vertebrates and sessile organisms competing for space, and in stable environments, than in small-bodied vagile invertebrates and in temporary or disturbed environments (Schoener 1986).

The reason why competition plays a more limited role than originally envisaged in the theory is rather straightforward: the theory was built from simple model systems and simplifying assumptions that are not encountered in nature. The theory implicitly assumed a closed, homogeneous, constant environment, and the absence of interspecific interactions other than competition. In nature, organisms live in open, heterogeneous, variable environments, and have various kinds of direct and indirect interactions with other organisms. We shall now consider how these other interactions and environmental conditions influence the structure and species diversity of communities.

4.5.3 Predation and mutualism as diversity-maintaining processes

As an additional source of mortality, predation usually has obvious direct negative effects on prey populations: it tends to reduce population size, generate instability and population cycles (May 1973), and hence increase the risk of population extinction. Other forms of exploitation of one organism by another, such as herbivory, parasitism and disease, have similar negative effects. Predation can also have indirect negative effects on prey populations. If two prey species share the same predator, consumption of one species contributes to increase the predator population and

hence the predation pressure on the other species. In this way, predation mediates an indirect negative interaction between prey species, which has been variously called 'apparent competition' (Holt 1977, 1984) or 'competition for enemy-free space' (Jeffries and Lawton 1984). Through such negative effects, predation and other forms of exploitation tend to reduce local prey or host species diversity.

Yet exploitation can also be a powerful factor enhancing species diversity. Darwin (1859) already noticed that the mowing of a lawn or its browsing by large herbivores could maintain a higher richness of plants than occurred in its absence. Paine's (1966) experiment in the rocky intertidal zone of the Pacific coast of North America established conclusively the importance of predation in the maintenance of prey species diversity. After removal of the top carnivore, a starfish, the number of prey species collapsed from 15 to eight, and a single species, a mussel, covered almost the whole experimental site. The top predator played the role of a keystone maintaining the arch formed by the entire community, hence the name of 'keystone species' to designate such organisms (Paine 1969; see Box 5.2-1 for the modern definition). The mechanism underlying the maintenance of species diversity by predation was made clear experimentally by Lubchenco (1978) with a herbivorous periwinkle snail in another rocky intertidal region. She showed that the periwinkle increased algal diversity when its preferred algal species was competitively dominant, while it decreased algal diversity when its preferred algal species was competitively inferior. Thus predation enhances prey diversity when it counteracts interspecific competition among prey species. By selectively reducing the populations of competitively dominant species, it prevents competitive exclusion of the inferior species and hence benefits the latter indirectly. On the other hand, when predation is heavier on competitively inferior species, its negative effects add to those of competition and further contribute to the exclusion of these species, thereby reducing prey diversity. Note that predation-maintained diversity does not always imply the action of a single keystone predator: sometimes it results from the combined action of several predators, each of which has only a weak effect. This has been called 'diffuse predation' (Menge and Lubchenco 1981; Menge *et al.* 1994).

For a predator, it will be advantageous to specialize in prey that are abundant and not very resistant to predation. Since there is generally a trade-off between competitive ability and resistance to predation (which requires resource allocation to the production of physical, chemical or behavioural defences), competitively dominant prey may often be less protected against predation than are other species. Therefore predators contributing to the maintenance of prey species diversity should not be an exceptional occurrence. Indeed, since Paine's experiment, keystone predators have been found to be common in intertidal communities (Paine 1994; Menge *et al.* 1994; Menge

Box 4.5-1: Why are there so many plant species in tropical rain forests?

The plant diversity of tropical rain forests is unrivalled. In the case of plants, for example, in Amazonian Ecuador, one hectare supports 473 tree species (Valencia *et al.* 1994) while, in Europe, North America and Asia, temperate forests collectively cover 420 000 000 ha yet support just 1166 tree species (Latham and Ricklefs 1993). Although poorly studied, herbaceous understorey plants also form very diverse communities. The highest plant species density yet recorded, 365 species in 0.1 ha, was realized in the only complete enumeration of all plants in a tropical rain forest (Gentry and Dodson 1987). A variety of ecological processes contribute to this diversity, processes that in some cases are being disrupted by human activities.

The sombre understoreys of tropical rain forests are punctuated by openings created when a tree falls, perhaps dragging several of its neighbours to the ground. The resulting spatial heterogeneity provides the potential for plant species to specialize in different light intensities from the open centre of a treefall to the deeply shaded understorey, to different positions along the fallen tree associated with differences in substrate stability (Núñez-Farfán and Dirzo 1988), or to different soils from exposed clays where roots tip up to rich humic material where canopy leaves and branches decompose (Denslow 1987; Orians 1982). There is some empirical evidence for the existence of a variety of life-history types among tropical tree species in relation to treefalls: light-demanding pioneer species tend to germinate, establish and grow to maturity only in gaps, while non-pioneer or climax species tend to germinate and establish primarily in the shade, often attaining maturity when juveniles are released from suppression (Martínez-Ramos *et al.* 1989; Alvarez-Buylla and Martínez-Ramos 1992). Human alteration of the natural disturbance regime is then likely to reduce the number of coexisting species (Alvarez-Buylla and García-Barrios 1993). However, most plant species seem to respond similarly to treefall gaps, their performance improving with light levels (Denslow *et al.* 1990; Osunkoya *et al.* 1992). Preliminary data suggested that fewer than 25% of tropical rain forest species depend on light gaps for their performance and survival (see Martínez-Ramos 1994). But in repeated rigorous surveys of the performance of 250 000 trees in Panama, the great majority of species survived well and grew slowly both in treefall gaps and in the deeply shaded understory, and just 5% were specialized to treefall environments (Welden *et al.* 1991). Thus, spatial heterogeneity associated with treefalls seems to make a small contribution to tropical forest plant diversity.

The depredations of plant pests may be of greater significance. Plant pests include pathogens, insects and vertebrates that consume plant tissues. Even relatively small levels of insect damage are important because they promote pathogenic infection (Dirzo 1987). Plant pests act to increase plant diversity when they attack a superior competitor and thus prevent competitive dominance, or when they eliminate the dense congregations of seeds and seedlings that accumulate beneath fruiting plants, thus preventing regeneration of conspecifics in close proximity (Gillett 1962; Janzen 1970; Connell 1971). Herbivores do appear to reduce seed and seedling congregations in tropical forests (Clark and Clark 1984; Howe 1990). When herbivorous mammals are extirpated by hunting or habitat destruction (Dirzo and Miranda 1991) or excluded experimentally (Terborgh and Wright 1994), the dynamics of plant regeneration are altered dramatically, with large increases in the total density of seedlings and the development of single-species seedling carpets beneath fruiting plants. The movements of pathogens and insects from nearby adult plants may also reduce the survivorship and growth of saplings as large as 8 cm in diameter at breast height (Hubbell *et al.* 1990). Plant pests clearly alter the regeneration of tropical forests, and may contribute to maintain their high plant diversity.

It is unclear, however, how pest pressure might be related to the strongest gradient in plant diversity observed among tropical forests. The diversity of all vascular plant life forms increases with rainfall throughout the tropics (Whitmore 1975; Hall and Swaine 1981; Gentry 1988; Clinebell *et al.* 1995). Gross primary production of tropical forests also increases with rainfall (Brown and Lugo 1982; Jordan 1983; Medina and Klinge 1983). Plant diversity is greatest in the most productive tropical forests. There are at least two possible explanations of this pattern. First, rates of tree turnover and treefall formation are higher in more productive forests, leading to a more heterogeneous environment and thence to higher diversity (Grubb 1986; Phillips *et al.* 1994). We have seen, however, that just a few percent of tropical forest plant species are specialized to this type of spatial variation (Hubbell *et al.* 1990). Alternatively, the most productive forests occur where rainfall and soils are most favourable for plant growth. Here, the physiological requirements for moisture and mineral nutrients are fulfilled for the greatest number of species and relative allocation can be shifted from roots to photosynthetic functions, permitting the greatest number of species to maintain a positive carbon balance and regenerate from the shaded understorey (Gentry and Emmons 1987; Wright 1992).

Box 4.5-1 cont.

The clear-cutting of large tracts of tropical forest has received wide publicity (Myers 1992). Characteristics of the remaining forests and human impacts on those forests are less widely appreciated. Dry and moist tropical forests are often most suitable for agriculture and have suffered the most rapid rates of deforestation throughout the tropics (Brown and Lugo 1982). Fortunately, several tracts of the tropical rain forests that maintain the greatest diversity of plants and other taxa are relatively intact. Herbivorous mammals are, however, being hunted to local extinction over large areas of tropical rain forest with potentially grave consequences for forest regeneration and the ongoing maintenance of plant diversity (Redford 1992). The wetter tropical forests that harbour the greatest plant diversity are also coming under increasing pressure from expanding human populations throughout the tropics. Conservation and the development of technologies appropriate to sustainable use of these most diverse forests are urgently required.

1995). In grasslands, mowing or grazing by mammal herbivores are generally indiscriminate, but they affect most strongly those plants that grow tall and fast, and thus have the same effect as selective predation on competitive dominants. Grazing by sheep has long been known to maintain high plant species diversity and prevent the successional conversion of grasslands into forests. Grazing and mowing are being used in the conservation of threatened chalk grasslands in Europe (Bobbink and Willems 1988).

Two other powerful mechanisms contribute to the maintenance of prey species diversity by predation. The first is prey switching, in which the predator feeds disproportionately often on food items that are common, and switches its preference when those food items become rare. This type of frequency-dependent predation always acts selectively against abundant prey, and thus enhances the stability and diversity of prey communities (Murdoch and Oaten 1975). Frequency dependency is also likely in host mortality induced by parasites and disease because of increased transmission rates at high host density, leading to an increased potential for host species coexistence (Holt and Pickering 1985; Anderson and May 1986; Combes 1995).

The second powerful mechanism by which predation can maintain prey species diversity is spatial aggregation of predation. This is generally known to exert a strong stabilizing effect on predator-prey or parasite-host interactions (May 1978; Beddington *et al.* 1978; Hassell 1978; Hassell and May 1988). It has also been put forward as a key factor in maintaining the high richness of tree species in tropical forests. Janzen (1970) and Connell (1971) proposed that predation on seeds and seedlings is disproportionately high close to adult trees because host-specific consumers tend to concentrate in areas where food density is highest. Since seed density drops rapidly as the distance from the adult tree increases, tree recruitment should be highest at some intermediate distance from the adult tree, where the balance between decreased seed density and increased seed survival is most favourable. This hypothesis helps to explain both the high species diversity and the spatial heterogeneity

characteristic of tropical forests, and has received support from a number of studies (Box 4.5-1).

Species other than predators can play the role of keystone species and contribute to the maintenance of species diversity. A keystone species can be defined more generally as a species whose impacts on its community or ecosystem are large, and much larger than would be expected from its abundance (Power and Mills 1995; Sections 5 and 2.3 and Box 5.2-1). Although the concept has sometimes been used too broadly or vaguely (Mills *et al.* 1993), it usefully places emphasis on species that have a small biomass and yet play critical roles in their communities or ecosystems, and which, therefore, should be included in conservation priorities (Bond 1993). It also reminds us of the importance of non-trophic interactions in communities and ecosystems. Many species are important to others not because they feed upon them or are fed upon by them, but because they provide their physical environment ('structural species' – Huston 1994), modify their physical environment ('habitat modifiers' or 'ecosystem engineers' – Owen-Smith 1987; Jones *et al.* 1994) or provide them with diverse benefits such as protection or dispersal (various mutualists).

Mutualism, an interaction between organisms that brings mutual benefit, has received relatively little attention in ecology; yet it is extremely widespread and important to the persistence of organisms and populations, hence to the maintenance of biodiversity. 'A very significant proportion, probably most, of the world's biomass depends on it – for example, the dominant organisms of all grasslands and forests (plant roots intimately associated with fungi in mycorrhizae), and corals (animal polyps containing unicellular algae) are mutualists. Most rooting plants have mutualistic mycorrhizae; many flowering plants depend on insect pollinators; and a very great number of animals possess guts which contain a mutualistic community of microorganisms' (Begon *et al.* 1990). Mutualistic relationships are very diverse, and differ widely in their degree of dependency, ranging from facultative interactions, through interactions that are obligate for one or both partners, to

symbiosis, i.e. an intimate physical association between organisms (such as lichens or corals).

Facultative mutualism may be more frequent than previously thought. Recent research in African lakes, for example, shows that it is common in many feeding guilds of fishes in the form of exploitative co-operation (Takamura 1983; Hori 1987, 1991, 1993; Yuma 1993). Co-operation was also observed in their reproductive habits. Mutualistic relationships were even suggested between benthic animals and benthophagous fishes in these lakes (Nakai 1993). These kinds of facultative mutualisms can promote biological diversity (Matsuda *et al.* 1993, 1994).

Many plants depend on animals for their pollination and seed dispersal. Such obligate mutualistic relationships are inherently fragile when they are specialized; if the population density of one of the partners drops below some threshold, the two partners may be driven to extinction (May 1976; Wolin 1985). Some of the species involved in these interactions may be keystone species, which contribute to the maintenance of a large number of other species in tropical rain forests (Gilbert 1980). As an example, the canopy tree *Casearia corymbosa* in Costa Rica supports several obligate fruit-eaters that depend on it almost entirely during the 2–6 week annual scarcity of fruit (Howe 1977). The loss of that tree species is expected to lead to the disappearance of several bird species, which would in turn have consequences for the other tree species whose seed they disperse during the rest of the year (Howe 1977).

Mutualistic interactions, in particular symbiosis, also produce some new biological traits that cannot be attained by either of the partners alone. These 'synergetic traits' are biological 'innovations' which contribute to enhance biological diversity. For example, neither termites nor their symbionts (bacteria, protozoa and fungi) alone could process the vast amount of litter (dead plants) in tropical forests and savannahs. But in association with each other, they become 'superdecomposing machines' in tropical terrestrial ecosystems (Brian 1978; Higashi and Abe 1993). Progress in symbiosis may lead to a closer biological association accompanied by gene transmissions and thus changes in the DNA, and even ultimately to unification (fusion). This process is a source of novel genetic diversity.

4.5.4 How species are interdependent through manifold indirect interactions

Ecosystems are very complex systems in which many different organisms and species interact. Each organism interacts directly with only a limited number of other organisms through such processes as interference competition, predation and mutualism, but the consequences of its direct interactions extend far beyond those particular organisms, because these in turn interact with still other ones, and so on. The ecosystem can thus be viewed as a complex interaction network in which each

organism or species transmits indirect effects to all other organisms and species (Higashi and Burns 1991). It is the whole network of interactions that results in the overall properties of the ecosystem, such as energy flows, nutrient cycling and trophic structure. The importance of indirect interactions in communities and ecosystems is an issue that has far-reaching implications for the maintenance and conservation of biodiversity. If indirect interactions are typically strong, the loss or addition of a species may have dramatic, possibly unpredictable, consequences on unrelated species. Simple theoretical arguments suggest that distant indirect interactions should generally be weaker than proximate or direct interactions for a system to be stable and preserve its structure (Levins 1970; May 1973; Simon 1977). The hierarchical nature of many ecosystem processes (O'Neill *et al.* 1986) tends to meet this constraint, at least at large spatial and temporal scales. However, this by no means precludes the importance of indirect effects, especially at small scales and within subsets of species.

That indirect interactions can be important should be obvious from the fact that most of the simple interactions we have so far discussed are actually indirect. Competition in its pure form of exploitation competition is an indirect interaction mediated by a shared resource: the competitors may never encounter each other. Apparent competition is an indirect interaction mediated by a shared predator. Keystone predators owe their keystone nature to the very fact that they benefit indirectly prey which they do not consume. But several other forms of indirect interactions among a few species have been identified. Thus, two competing species can be indirect mutualists if they both compete more strongly with a third species or if their resources themselves compete (Levine 1976; Lawlor 1979; Vandermeer 1980). In a plant–herbivore–carnivore food chain, the plant and the carnivore are indirect mutualists because the plant indirectly provides the food on which the carnivore feeds, while the carnivore reduces the herbivore density, hence the grazing pressure on the plant.

The latter form of indirect mutualism seems to be frequent and important enough to evolve into direct mutualistic relationships, as in the ant–acacia mutualism (Janzen 1967). Plants are not passive interactants but sometimes actively affect the other members of the system. When they are infested by herbivorous invertebrates, they can emit 'infochemicals' (information in the form of chemical substances) which stimulate diverse interactions. For instance, some plants release a 'cry substance' upon being attacked, which acts as an agent that summons the natural enemies of the herbivores (Dickie *et al.* 1990; Takabayashi and Dickie 1993). Furthermore, an attacked plant may cause its uninfested neighbouring plants to initiate defensive reactions (Bruin *et al.* 1991). This can result in 'hotspots' of relative immunity to the herbivore formed by undamaged plants in the neighbourhood of

the damaged plants, due to induced indirect defensive actions.

Exploitation competition can also be much more indirect, asymmetrical and subtle than traditionally considered. Competitive interactions occur between herbivorous insects that are very distinct taxonomically and utilize different parts of the shared host plant in different ways, through changes in the quality and quantity of the host plant. Even insects feeding at different times or on different parts of a plant may have a substantial effect on the quantity or quality of their respective available resources. For instance, one species attacking the host plant early in the season can influence the performance or abundance of another species attacking late in the season, through changes in host quality. Such indirect effects mediated by the resource are more common than previously thought, notably in plant–insect systems (Faeth 1986; Loreau 1989a; Hunter *et al.* 1992). In general, complex interspecific interactions require the species involved to encounter and deal with a range of variations in interactions through time and space, thus promoting the diversity of their behaviours and adaptations.

The above examples concern indirect effects mediated by simple trophic interactions. Some important indirect interactions are much more distant and are mediated by ecosystem processes. In particular, nutrient cycling represents a circular causal pathway in ecosystems which transmits positive indirect effects to all ecosystem components. While direct trophic interactions are negative for the consumed organisms, the positive indirect interaction mediated by nutrient cycling may result in a net gain in productivity for those consumed organisms. As a rule, this occurs when consumers act to accelerate the circulation of nutrients within the ecosystem and their consumption is moderate (Loreau 1995). Thus, under these conditions, herbivores increase plant productivity, in agreement with the ‘grazing optimization hypothesis’ (Owen and Wiegert 1976; McNaughton 1979; Hilbert *et al.* 1981; DeAngelis 1992).

Given that indirect effects are certain to occur in communities and ecosystems, what is their frequency and relative importance compared with direct effects? Menge (1995) recently reviewed experimentally based studies from 23 rocky intertidal biotopes to answer this question. Although he considered only indirect effects mediated by simple trophic interactions, he identified 83 different kinds of indirect effects grouped into nine general types, of which keystone predation and apparent competition were most common, and he found that indirect effects accounted for 40–50% of the change in community structure resulting from experimental manipulations, with a range of 24–61%. Thus indirect interactions clearly are diverse, frequent and influential in intertidal communities. Such figures are unfortunately lacking for other communities.

One property of indirect effects is that they are often very sensitive to the values of the direct interaction

parameters (Bender *et al.* 1984; Yodzis 1988). Therefore, many of them are in principle difficult to predict, not only quantitatively but even qualitatively (Yodzis 1988). This means that the loss or addition of a species can have unpredictable effects on unrelated species, and potentially alter the whole interaction network. Past experience of species introductions tells us exactly this (Courtenay and Robins 1989; Carlton and Geller 1993). However, knowledge of the ecology of similar communities in conjunction with limited experiments and adequate analysis methods offers the promise of greatly enhancing our ability to predict significant indirect interactions (Wootton 1994; Menge 1995).

Food-web theory also offers some predictions on the potential effects on the rest of the community of species removal or addition. Pimm (1991) predicted that the species composition of complex food webs will be most resistant (least sensitive) to the loss of species at their base (plant species, for instance) and least resistant to the loss of their top predators. The results are expected to be reversed for simple food webs (Figure 4.5-1). ‘Complex communities should be most sensitive to the loss of species from the top of the food web, because secondary extinctions propagate more widely in complex than in simple communities. Simple communities should be more sensitive to the loss of plant species than complex communities, because in simple communities the consumers are dependent on only a few species and cannot survive their loss. The introduction of trophically generalized species should have profound effects on community composition, because such species can eliminate many of the species on which they feed. Specialized species should produce fewer changes’ (Pimm 1991). However, the evidence for these theoretical predictions is anecdotal and open to alternative explanations. For instance, Pimm compares the consequences of the loss of plant species on oceanic islands and on continental landmasses and notes that the simpler island food webs seem less resistant to plant loss. But this difference may also be due simply to an insular effect. Thus our ability to predict the long-term consequences of species losses or introductions on existing communities is still limited due to the manifold potential indirect interactions among species. This commands caution in attempts to manage biodiversity.

4.5.5 *The role of spatial and temporal variability of the environment in the maintenance of biodiversity*

Although the natural world is obviously heterogeneous and variable, until recently most ecological theories have been based on a view of a homogeneous and constant world inherited from classical physics. The implicit rationale for this simplification is that the behaviour of a homogeneous and constant system should approximate the average behaviour of a spatially and temporally variable system. While this is true for some processes considered at

Figure 4.5-1: The effects of the elimination of one species on other species depends on the structure of the trophic network and the position of the species in the network. The extinction of a plant species at the base of a simple trophic chain can result in the disappearance of the entire network (a), while the removal of a predator from the top of the same network will have no effect (b). On the other hand, if the trophic network is more complex, the loss of a low level plant species can take place without consequences (c) whereas loss of a predator (d) can indirectly result in the extinction of several plant species (after Pimm 1991).

appropriate scales, it also hides important non-linear dynamic processes responsible for the coexistence of species. During the last two decades, spatial and temporal variability of the environment has increasingly been recognized as a major determinant of species diversity in communities and ecosystems.

As already mentioned above, spatial heterogeneity has generally been found to exert a strong stabilizing effect on predator-prey and parasite-host interactions (May 1978; Beddington *et al.* 1978; Hassell 1978; Hassell and May 1988). Similarly, it has been found often to increase the potential for coexistence between competing species (Hanski 1981; Ives and May 1985). It is considered by some to be one of the major factors explaining patterns of species diversity among communities at a regional scale, notably the common hump-shaped relationship between diversity and productivity (Rosenzweig and Abramsky 1993). It is regarded as being particularly important in plants. Since most plants depend on the same basic limiting resources – light, a few nutrients and space – the potential for niche differentiation seems to be much more limited for plants than for animals. How then to explain the

coexistence of so many competing plants, in tropical forests for instance?

Environmental heterogeneity is one of the possible answers: it can intervene through several mechanisms. First, the competitive ability of plants competing for nutrients is determined by the ratio in which the various nutrients are available; if this nutrient ratio is spatially variable, different plants will persist in different places, so that plant diversity can be high over a large enough area (Tilman 1982). Second, sessile organisms such as plants deplete resources only in a finite volume around them; if nutrients limit plant growth, competition for nutrients among plants will hinge upon the rate of nutrient transport between the local nutrient depletion zone around each plant's root system and the overall nutrient pool in the rest of the soil, so that many species can coexist at moderate transport rates (Huston and DeAngelis 1994). Environmental heterogeneity is then created by the organisms themselves; it is not a passive property of the environment. Third, even if the environment itself is homogeneous, the dynamics of colonization of vacant sites and individual death for sessile organisms such as plants

are likely to prevent complete monopolization of space by a single species and result in a shifting mosaic of diverse species, provided that there is a trade-off between competitive ability and colonization ability among them (Tilman 1994).

Temporal variability of the environment plays an equally important role. The equilibrium paradigm that dominated ecology until roughly twenty years ago has since then been challenged and eventually complemented by non-equilibrium concepts (DeAngelis and Waterhouse 1987; Huston 1994). There are several ways by which a variable environment can enhance species coexistence. If the time scale of significant environmental changes (such as seasonal changes in temperature or resource availability) is roughly the same as that of competitive exclusion between species, and if various species thrive under different environmental conditions, no species will ever be able to bring competitive exclusion to completion, so that many species can coexist on the same resource without reaching a competitive equilibrium (Hutchinson 1961; Chesson 1986). Levins (1979) showed that permanent, indefinite non-equilibrium coexistence is possible among species competing for the same resource provided that each species is limited by a different statistical moment of resource dynamics. But competing species may also be unable to coexist indefinitely, whether at equilibrium or far from it, and yet be able to avoid competitive exclusion so long as their persistence is governed by processes acting at biogeographical spatial scales and historical time scales. In particular, the more species that are competitively equivalent, the longer the time required to achieve competitive exclusion. Competitive equivalence among tree species has been suggested as one of the explanations for the maintenance of the high diversity of tropical forests (Hubbell and Foster 1986). Competitive exclusion can also be retarded by recurrent disturbances reducing population densities: it is expected to be slowest, and thus species diversity to be highest, at intermediate frequencies of disturbance and intermediate rates of population growth (Huston 1979; see also below).

Disturbances which open up gaps are of special significance to sessile organisms which have a requirement for open space. Disturbances may be either physical (e.g. storms, fires, earthquakes) or biological (e.g. predation, trampling by animals, tree falls). Their common action is to remove organisms, open up space which can be colonized by other organisms, and usually initiate a local mini-succession. The dynamics of recurrent disturbance and colonization then creates an ever-changing patchwork of successional stages (Pickett and White 1985). Spatial heterogeneity and temporal variability are here linked intimately: communities are viewed as a dynamic and heterogeneous mosaic of patches. Although patches are constantly changing as a result of succession towards a

climax, patch dynamics tends to attain a large-scale equilibrium under a constant regime of natural disturbance. This equilibrium, called the 'shifting mosaic', is characterized by a constant statistical distribution of patches in time and in space at the scale of the landscape (Pickett and White 1985). However, fluctuations in environmental factors that affect patch dynamics often tend to bring the community away from the equilibrium state. For example, in tropical rain forests, the main factor determining patch dynamics is gap formation by tree falls. These increase with increased precipitation, and thus fluctuations in the yearly amount of rain cause significant and correlated temporal fluctuations in the regime of disturbance.

Natural disturbances potentially span a wide range of temporal and spatial scales. What defines a disturbance versus a normal component of a system is very much scale- and context-dependent (see Section 5.3.1). The effects of disturbances are similar to those of some biological processes we have already discussed, such as keystone predation in rocky intertidal sites (which can actually be viewed as a kind of disturbance from the perspective of prey communities) or death of individuals in communities of sessile organisms. All those processes act to open up space for colonization by other organisms, and thus make a higher diversity of coexisting species possible. The 'intermediate disturbance hypothesis' (Levin and Paine 1974; Horn 1975; Connell 1978) proposes that the highest diversity is maintained at intermediate levels of disturbance. If disturbances are very frequent, gaps will be constantly reset to an early successional stage, and only pioneer species will be present. If disturbances are very rare, most of the community for most of the time will remain at the climax state, and competitively superior, climax species will dominate. At intermediate frequencies of disturbance, gaps and species from all successional stages will be present, and hence diversity will be highest. This hypothesis has been proposed as one explanation of the high diversity of tropical rain forests and coral reefs (Connell 1978), but recent evidence suggests that it is only a small part of the story (see Box 4.5-1). It has implications for the sustainable use of ecosystem components, in that ecosystems might be able to support a certain amount of disturbance in the form of controlled intervention without significant reductions in biodiversity.

The growing recognition of the significance of spatial and temporal variability in communities and ecosystems, the development of the equilibrium theory of island biogeography (MacArthur and Wilson 1967), and the failure to explain global patterns of biodiversity by local environmental conditions, have recently led to a greater emphasis on processes occurring at large spatial and temporal scales in community ecology. A local community – on whatever scale it may be defined – is affected not only

by small-scale interactions such as competition, predation and mutualism, but also by large-scale regional processes and unique historical and geographical circumstances, which influence the number of species it contains (Ricklefs 1987; Ricklefs and Schluter 1993). Over a landscape, diversity depends on the spatial dynamics of patches and biotopes and the dispersal properties of populations. Within larger regions, processes that determine the production of species over evolutionary time come into play. These geographical and historical dimensions of local biodiversity are discussed in Section 3.3: accordingly they will not be developed here.

4.5.6 From ecosystems to genes: the role of coevolution in the generation of biodiversity

The continued interaction between organisms and their natural environment is not only responsible for the maintenance of biodiversity; it also contributes to the generation of novel biological traits and functions. A simple but clear example of an interaction with the environment promoting biodiversity can be found at the cellular and molecular level in the immunological responses of an organism to alien materials invading the body. The diversity of antibodies and sequences of restructured DNA produced in immunological cells results from the necessity to counter the diversity of potential antigens present in the environment.

The many intra- and interspecific biological interactions within communities and ecosystems play an important role in the evolutionary generation of biodiversity. All organisms have evolved in response to selection pressures, of which a significant part originates from other organisms. Thus, all organisms are likely to have coevolved with other organisms to some extent, though the latter are not necessarily those with which they interact now. Coevolution is usually defined as a reciprocal evolutionary change in traits of two species as a result of their interaction (Janzen 1980), but the concept could apply to interactions among more than two species as well.

Since Ehrlich and Raven's (1964) classic paper on coevolution between butterflies and plants, many examples of coevolved traits have been suggested in plant-animal interactions. Through selection and evolution, plants develop defence systems that prevent or reduce attacks by a variety of herbivores. The hard structures made of cellulose and other cell-wall substances serve as a basic physical defence, whereas the secondary substances stored in the cytoplasm are effective chemical defences (Abe and Higashi 1991). Animals attacking plants develop means for coping with these defences, also through selection and evolution. An evolutionary arms race then takes place. This coevolutionary process may lead to the creation of amazing products on both sides. This is a good example of how species interactions, through co-evolutionary processes,

generate novel biological traits and thus enhance biodiversity. In the absence of herbivores, plants tend to reduce and eventually cease their production of secondary defence compounds because of the high costs necessary to continue such production. Thus, interactions with animals are necessary for the continued production of those substances. This shows that some biological traits cannot be maintained when an organism is kept alone, out of its proper biological environment.

Coevolution is likely to be particularly important in systems composed of a host and an associated organism. A large proportion of the known species are organisms (parasitoids, parasites, commensals and mutualists) that are associated with, and require the continued interaction with, a host. Actually, there does not seem to be any animal or plant group in which such host-associate interactions are absent. The host provides the 'habitat-resource' system that controls the evolution of its associated organisms, and the latter impose selective constraints on the host. Thus, coevolution is an almost inevitable outcome of such interactions. Coevolution in host-associate systems can be studied in two different ways. First, the genomic components of the host and its associate may be compared. This comparison is based on the concept of a 'gene-for-gene' correspondence between resistance in the host and virulence in the parasite or pathogen (Flor 1956). This mode of coevolution between partners has been reviewed by Barrett (1985) and Thompson and Burdon (1992). Second, direct examination of the species themselves sheds light on the role of co-speciation in the generation of biodiversity. Co-speciation, the concurrent production of new species in hosts and their associates, is a remarkable form of coevolution, which may represent a significant source of novel biodiversity in host-parasite systems (see Box 4.5-2).

4.5.7 Towards an integrated approach

Developments in community ecology during the last two decades have made it clear that no single factor (competition, abiotic factors, disturbances, etc.) can account for the whole structure and species diversity of communities. Abiotic factors, biological interactions such as competition, predation, parasitism and mutualism, and their various indirect effects, ecosystem processes, temporal and spatial variability of the environment, regional processes and historical contingency and evolutionary processes, all have to be taken into account to varying degrees to explain the diversity of species in any local community or region (Figure 4.5-2; Diamond and Case 1986; Gee and Giller 1987; Begon *et al.* 1990; Barbault 1992; Ricklefs and Schluter 1993; Huston 1994). Ecological theory is in a period of profound restructuring and synthesis in which different theories on the origins and maintenance of biodiversity are being integrated. The outcome of this

Box 4.5.2: Generation of biodiversity in host–parasite associations.

Co-speciation is generally held to play a key role in host–associate evolution (see Brooks and Mc Lennan 1991 for a review), and thus to be a significant evolutionary source of biodiversity in host–associate systems. In this mode of evolution, speciations in the two partners are concomitant, so that the phylogeny of one mirrors that of the other (Figure A, opposite). However, this process has not been well documented. Its only demonstrative study is a comparative analysis of genetic divergence among 15 species of rodents and 17 species of associated ectoparasites (chewing lice). Comparison of phylogenies, based on enzymatic polymorphisms and the DNA sequences of the gene coding for mitochondrial cytochrome oxidase, suggests that co-speciation is the rule in this association (Hafner and Nadler 1988; Hafner *et al.* 1994). Such an analysis also allows comparison of the rates of evolution of the host and parasite genomes and quantification of the levels of nucleotide divergence which, in this case, appear to be different in hosts and parasites.

In the strict sense of the term, co-speciation implies that a single parasite species is associated with each host species. The fact that the above study is so far the only one to have demonstrated it may reflect a lack of research in this field, or it may indicate that strict co-speciation is only a minor process in the evolution of host–associate interactions. Alternative processes are possible. Thus, several congeneric parasite species often co-exist in one host species. For instance, the teleostean *Alestes nurse* (Characidae) hosts on its gills a record eight congeneric species of monogeneans belonging to the genus *Annulotrema* (Birgi and Euzet 1982). Similarly, in the western Mediterranean, three congeneric species of teleostean fishes (Mugilidae) are parasitized by, respectively, two, three, and four host-specific, congeneric species of monogeneans belonging to the genus *Ligophorus* (Euzet and Sanfilippo 1981). In such cases, there are secondary speciations of parasites within a host species leading to an enrichment of parasite diversity. This phenomenon can be compared to gene duplications in genomes (Page 1994).

The above processes result in phylogenetic development of biodiversity. But non-phylogenetic processes also can contribute to increased biological diversity. Just as there are horizontal gene transfers between different genomes (insertion sequences), there are lateral transfers of parasite taxa between host lineages (host switching – Figure B, opposite). Such lateral transfers increase the parasite richness of the target lineage, and can cause subsequent speciation of its parasites. Host and parasite phylogenies, analysed after this process has taken place, can be very different. Even in the rodent–chewing lice association showing co-speciation, there are two known cases of lateral parasite transfer between host lineages. Hoberg (1986) suggested that the diversity of a bird (Alcidae) – cestode (Dilepididae) system evolved mainly by switching between host lineages. These lateral transfers can involve various processes – ecological, ethological, or biogeographical (Euzet and Combes 1980; Brooks and McLennan 1991). They are well known in the case of humans; as these occupied new areas of the planet and domesticated other animals, they acquired parasites of various origins (such as *Schistosoma*, *Trypanosoma*, etc.).

Other potential mechanisms involved in the evolution of host–parasite systems were suggested by a recent work of Verneau (1994) on co-speciation in an association between six teleostean fish species and their six host-specific endoparasite cestod species. Quantification of nucleotidic divergence by DNA/DNA hybridization in liquid phase and sequencing of part of rDNA 18S between pairs of hosts and parasites showed that co-speciation and lateral transfers were not the processes likely to govern the evolution of this system. Indeed, the smallest nucleotide divergence observed between host pairs was greater than the largest nucleotide divergence observed between parasites pairs. Yet the rates of evolution of hosts and parasites, analysed on the basis of rDNA 18S sequences, were not significantly different. Therefore, the speciation of these six parasite species, and thus the enrichment of biodiversity in the system, must have been produced in a very short time period, totally independently of their hosts, whose origin is far more ancient. Two hypotheses could explain these results: either sequential colonizations of different host species and subsequent speciation of parasites, or an explosion of an ubiquitous parasite species into a complex of host-specific species.

Such evolutionary processes are of prime interest for research into the palaeoclimatic and geological events which have marked the history of the Earth and shaped the present biological diversity. Periods of extinction or diversification of organisms over geological time should also be periods of extinction or diversification of their associated organisms. The understanding of the origins of the biological richness in host–associate systems provides a new potential line of research into the evolutionary history of organisms for which the fossil records will never be sufficiently informative to support viable hypotheses.

process should be a more unified theory that takes the many potential factors into consideration.

One attempt at integrating the various factors determining community structure and species diversity was made by Schoener (1986), who proposed to rank communities along primitive axes, defined by both organismic properties (body size, recruitment, generation time, individual motility, homeostatic ability, number of life stages) and environmental properties (severity of physical factors, trophic position, resource input, spatial fragmentation, long-term climatic variation, partitionability of resources). Derived axes then order ecological characteristics whose patterns are explained in terms of the primitive axes. Examples are the relative importance of physical versus biological processes, the relative importance of predation versus competition, the number of species, and the relative importance of history. In a similar vein, Menge and Sutherland (1987) proposed a model of community regulation predicting the relative importance of disturbance, competition and predation in relation to variation in environmental stress, recruitment density and trophic position. Here also, it is increasingly recognized that such patterns depend on a complex interplay between regional- and local-scale processes (Menge and Olson 1990).

Thus, in this process of integration, care must be taken to avoid the drawbacks of many classical community approaches, namely: (1) failure to link community and ecosystem processes; (2) disregard of the temporal, historical and evolutionary dimensions of the problem, notably the phylogenetic relationships between taxa (Brooks and McLennan 1991); and (3) lack of representation of spatial frameworks, with their heterogeneity at various scales, from microhabitat to landscape. The temporal and spatial dimensions of

biodiversity dynamics are considered explicitly in Wien's (1989) scheme of community assembly (Figure 4.5-3).

To face the challenge raised by the loss and management of biodiversity, a space- and ecosystem-oriented approach appears to be more useful and efficient than an accumulation of species-centred studies. Species richness and genetic variability are closely linked with ecosystem and landscape properties, such as biotic interactions, habitat diversity, spatial heterogeneity, disturbance regime, patch dynamics, etc. In this context, a landscape ecology approach is useful, because it helps in dealing with environmental heterogeneity in spatially explicit terms, as well as linking spatial patterns and processes (O'Neill and Shugart 1987; Turner 1989; Zonnerveld and Forman 1990; Wiens *et al.* 1993; Barbault 1994, 1995). This approach may also offer an appropriate tool to conserve the vast majority of biological diversity (Franklin 1993).

One message that emerges from this chapter is that the rich complexity of both the physical environment and the interactions among organisms and species is crucial for the maintenance and generation of the diversity of their biological traits (biochemical, physiological, behavioural, and other). Ecological complexity enhances biodiversity through slow evolutionary and biogeographic processes, whereas its degradation (the simplification of ecological interactions and habitat structure) tends to result in a fast decline in the diversity of phenotypic and genotypic traits. For the conservation of biodiversity, it is not sufficient to preserve living organisms or their gametes in isolation. Keeping animals and plants in zoological and botanical gardens or frozen as gametes cannot conserve the full range of biological diversity they exhibit in nature, because they lose the ecological complexity that they enjoy in their original habitats. To preserve the full biodiversity

Figure 4.5-2: The diversity of factors usually called upon to explain the latitudinal gradients of fauna and flora richness, made more complete by the addition of human disturbances, should constitute the framework of a pluralist theory of historical and ecological determinism of biodiversity levels and dynamics (from Barbault 1992).

embodied in living organisms, these must be maintained in, and together with, their natural environment, *in situ*, with the proper ecological complexity and dynamics.

4.5.8 Summary

Biodiversity cannot be properly understood without due consideration of its dynamics in communities and ecosystems. Interactions among species play an essential role in the generation and maintenance of biodiversity. Interspecific competition tends to limit the number of coexisting species on an ecological time-scale, but also to increase niche differentiation among species, and thus to diversify species' traits on an evolutionary time-scale. Although predation has direct negative effects on the prey consumed, it can also be a powerful factor enhancing prey species diversity. Keystone predators, which maintain high prey species diversity by selectively reducing populations of competitively dominant species, appear to be common in several ecosystem types. Mutualistic interactions are extremely widespread and important to the persistence of species. Some mutualists may also be keystone species, which contribute to the maintenance of a large number of other species. Additionally, many other indirect interactions bind organisms together in ecosystems. Therefore, the loss or introduction of a single species or

group of species can have far-reaching effects on many other species and the ecosystem as a whole. The continued interactions among organisms are not only responsible to a significant extent for the maintenance of biodiversity, but also for its evolutionary generation. The co-evolution of species tends to produce novel biological traits: it is likely to be particularly important in host-associate systems, where it can take the form of co-speciation.

Spatial heterogeneity and temporal variability of the environment are also major factors determining the maintenance of biodiversity in communities and ecosystems. Environmental heterogeneity allows potentially more species to coexist, and may be especially important in the maintenance of the diversity of plants and other sessile organisms. Temporal fluctuations of the environment also increase the potential for coexistence of species. In particular, disturbances which open up gaps are of great significance to sessile organisms which have a requirement for open space. The dynamics of recurrent disturbance and colonization creates a shifting mosaic of patches at different successional stages, which tends to maintain highest species diversity at intermediate levels of disturbance. Species diversity depends also on regional, biogeographical, historical and evolutionary processes occurring at large spatial and temporal scales.

Thus, the rich complexity of both the physical environment and the interactions among organisms and species appears to be crucial for the maintenance and generation of biodiversity. It is traditional in conservation biology to focus on individual populations or species that are endangered. However, the species, though important, may not be the best overall target for conservation. The ecosystem and its component communities which contain the species appear to be more appropriate targets for conservation, because they take into account explicitly the many ecological interactions between organisms and their biotic and abiotic natural environment. A space-orientated approach up to the landscape scale may be the most appropriate tool with which to conserve the vast majority of biological diversity.

EXECUTIVE SUMMARY

The chapters in this section explore the ways in which diversity, at various levels, influences the functioning of ecosystems and how this, in turn, relates to human needs.

1. Ecosystems are composed of all the individuals of all the species in a given area, and their physical environment. Ecosystems provide free services to society including clean water, pure air, soil formation and protection, pest control, foods, fuel, fibres and drugs.
2. The loss of genetic variability within the populations of a species in a given area reduces the flexibility of those species to adjust to environmental changes (such as climate changes, for example) and narrows the options available for the rehabilitation of specific habitats.
3. The addition or deletion of a species can have profound effects on the capacity of an ecosystem to provide ecosystem services.
4. We are beginning to develop the capacity to predict which species will cause the greatest system impacts, and hence the greatest ecosystem service changes, when added or deleted.
 - (a) Species with unique traits for fixing nitrogen, capturing water, emitting trace gases, and so forth, when added or deleted will have profound effects on the functioning of an ecosystem. These effects can be predicted *a priori*.
 - (b) Certain other species, without readily recognized specialized traits, when added or deleted may also have profound effects on the capacity of ecosystems to provide services. These are so-called 'keystone' species. With our current state

of knowledge, their potential effects can only be assessed by direct experimentation.

5. Based on the latest evidence, the capacity of ecosystems to resist changing environmental conditions, and to rebound from unusual climatic or biotic events, is related positively to species numbers.
 6. Fragmentation and disturbance of ecosystems and of landscapes will have profound effects on the services provided, since these impacts shift the balance of the kinds of species present - from large, long-lived species to small, short-lived ones. These shifts reduce the capacity of the systems to store nutrients, sequester carbon and provide pest protection, among other things.
 7. The simplification of ecosystems to obtain higher yields of individual products comes at the cost of the loss of ecosystem stability and of free services such as controlled nutrient delivery and pest control, which thus need to be subsidized by the use of fertilizers and pesticides.
 8. Modification of ecosystems by the introduction of alien species, either deliberately or accidentally, has positive and negative ecosystem effects - but too often the latter because of the reduced biotic controls on the invading species.
 9. We have been more successful in simplifying than in reconstructing complex ecosystems. Our lack of success in ecosystem restoration suggests that great caution should be exercised in reducing biodiversity through management practices because of the potential loss of goods and services in the long term.
-

5.0 Introduction

5.0.1 Background

Does it make any difference to the functioning of an ecological system if there are many species or only a few? Are species that perform similar functions within an ecosystem interchangeable, or do they differ in ways that matter to the workings of the system? Does the genetic diversity of species affect the sustainability of ecosystem-level functions? How does diversity among ecosystems affect the flow of energy, water or chemicals across the landscape? What are the ecosystem-level ramifications of human-driven changes in biodiversity?

Addressing these questions requires an understanding of the relationships between biological diversity and ecosystem functioning, and thus the functional consequences of changes in biological diversity. The importance of this topic is underscored by the realization that the provision of marketable goods and free ecological services are essential features of humankind's interest in and benefit from the biosphere's diversity. The explosive growth of the human population and its use of resources, energy and land are resulting in massive changes in diversity at a variety of levels throughout the world. Some of these changes, such as extinction of species, are truly irreversible; while others are not, but the challenge of managing natural resources in a sustainable manner has clearly increased. Increases in our understanding of the relationships between changes in biological diversity and the functioning of ecosystems can help improve a wide range of policies involving agriculture, forestry, fisheries and land use, transcending traditional conservation-based policies. Assessing our knowledge of the general principles of the relationships between diversity and the functioning of ecological systems is the focus of this Section.

Understanding the functional implications of biodiversity requires that issues addressed in population and community ecology be merged with those in ecosystems ecology. Each of these areas of ecology has developed research traditions largely without interaction with the other. However, in the past decade, there have been a number of attempts to bridge these two approaches (Vitousek *et al.* 1987; Vitousek 1990; Schulze and Mooney 1993; Naeem *et al.* 1994; Tilman and Downing 1994; Jones and Lawton 1995). International scientific reviews by SCOPE (Mooney *et al.* 1995) aimed at understanding the relationship between biodiversity and ecosystem functioning, and the broader approach by the Diversitas programme of IUBS and UNESCO (Solbrig 1991) designed to also analyse the origins, maintenance and monitoring of diversity, have played a critical role in the preparation of Sections 5 and 6 of the GBA.

5.0.2 Important concepts

The term biodiversity has frequently been equated with diversity of species. The strength of the term is its

simplicity. However, understanding the functional significance of biodiversity necessitates teasing apart the rich and multiple dimensions of the concepts underlying the term (see Section 1). There are four key concepts to consider: (1) the levels of biological and ecological organization and their interactions, (2) the numbers of different biological units within each level, (3) the influence and degree of similarity in the traits or roles that biological and ecological units within each level play, and (4) the spatial configuration of the units within any level. For example, at the species level we need to consider whether there are functional consequences of the total numbers of different species, whether the degree of similarity in their functional roles or traits has ecosystem-level consequences, and whether the spatial configuration of the species influences ecosystem functioning.

Ecological systems can be viewed at increasing levels of organization: genetic, population, species, community, ecosystem and landscape. Patterns and processes at any particular level affect not only the target level, but also the levels above and below. Because ecosystems provide ecological goods and services to humanity, the assessment in the following chapters is focused generally on the ecosystem level, but includes relevant functioning at lower and higher levels.

We use the term 'ecosystem' to refer to all the individuals, species and populations in a spatially defined area, the interactions among them, and those between the organisms and the abiotic environment (Likens 1993; see Section 2.3). 'Ecosystem functioning' denotes the sum total of processes operating at the ecosystem level, such as the cycling of matter, energy and nutrients, as well as those processes operating at lower ecological levels which impact on patterns or processes at the ecosystem level. Interactions among species or the transfer of genetic material are examples of some of the lower level processes that are immediately relevant to the ecosystem consequences of biodiversity. Thus, in the following sections, patterns of diversity at the genetic, species, community and ecosystem levels are related to key functional properties of ecosystems.

Following other syntheses (Lubchenco *et al.* 1991), we use the term 'ecological system' to refer to the characteristics or functioning of organisms, populations, communities or ecosystems at a level that is appropriate to the particular questions being asked. Thus, it is analogous to the use of the word 'taxon' by systematists.

The roles of different species and the extent to which they overlap in function have been a common theme in community ecology. The concepts of 'keystone species', 'redundancy', 'compensation', 'functional groups' and 'rivets' all deal with the extent to which individuals or species overlap in function, and the consequences of this overlap to the system. An understanding of unique species'

traits, overlap among species, and the possible functional significance of low or high numbers of species, apart from how they differ in traits, is clearly immediately relevant to understanding the conditions under which 'species matter'. Historically less attention has been paid to the equivalent questions dealing with functional overlap among genes or ecosystems. Nonetheless, comparable information is now recognized as immediately relevant to conservation and management.

The third important topic of interest to the relation between diversity and the functioning of ecological systems is that of the spatial configuration of the units within the system. For example, knowing the consequences of different habitat or ecosystem configurations to the functional properties of landscapes would enhance the design of reserves as well as the management of resources. Knowing how the populations within an ecosystem are distributed in space would enhance our ability to predict its functional resilience to stress from pathogens and environmental variability.

5.0.3 Section organization

Chapter 5.1 begins with an exploration of the social and political context within which the study of biodiversity and ecosystem functioning occurs. Why should society care? In particular, it considers the notion that one of the very important aspects of ecosystem functioning that depends on diversity is the provision of goods and services, and the provision of insurance against adverse changes due to stress or environmental variability.

Chapter 5.2 then considers how the diversity of the natural world is organized, and how diversity at each level of organization affects ecosystem functioning. Subsection 5.2.1 addresses the question of the extent to which intraspecific genetic variation is important in understanding the relationship between biodiversity and ecosystem functioning; 5.2.2 addresses the degree to which we can predict the ecosystem-level consequences of species additions, deletions and replacements, and synthesizes the state of knowledge with respect to the processes that determine the importance of species and communities in ecosystem-level functioning; 5.2.3 addresses the spatial structure of populations, its effect on abundance, species interactions and life-history characteristics, and the subsequent consequences for ecosystem functioning and 5.2.4 analyses the larger spatial scales of landscapes and regions, in which human activities exert large influences, and considers how the relationships of diversity and functioning at these scales are similar to, or different from the relationships at other levels of organization.

Chapter 5.3 considers the drivers and dynamics of changes in biodiversity, and their subsequent consequences for ecosystem functioning. Subsection 5.3.1 assesses our knowledge of disturbance as a factor that

strongly affects the structure and function of ecological systems, and examines closely the role that different intensities and frequencies of disturbance have in determining species diversity within ecosystems, while 5.3.2 reviews the influence of human-driven changes in diversity due to changes in land use and resource use, atmospheric composition and climate change, and the potential or realized consequences for ecosystem and landscape/regional-scale functioning.

The Conclusion to Section 5 summarizes key findings and provides a synthesis of the general patterns and principles relating biodiversity and ecosystem functioning.

5.1 Context: biodiversity and ecosystem services

The conditions and processes characterizing natural ecosystems supply humanity with an array of free services upon which society depends. These include: maintenance of the gaseous quality of the atmosphere (which in turn helps to regulate climate); amelioration of the weather;

control of the hydrological cycle (including reduction of the probability of serious floods and droughts); protection of coastal zones by generating and conserving coral reef and sand dune systems; generation and conservation of fertile soils, which are essential to agriculture and forestry; dispersal and breakdown of wastes and cycling of nutrients; control of the vast majority of potential crop pests and vectors of disease; pollination of many crops, and direct provision of food from sea and land; and the maintenance of a vast 'genetic library' from which *Homo sapiens* has already extracted the very basis of civilization in the form of crops, domestic animals, medicines and industrial products (Ehrlich and Ehrlich 1981, 1992).

One of the most important questions in ecology – indeed, one of the most important ones facing humanity – is the degree to which some overall level of biodiversity is required for the delivery of ecosystem services (Ehrlich 1993). This question is ordinarily interpreted to mean 'what is the minimum fraction, of the estimated 13.5 million species now extant, required to keep ecosystems functioning so that they can continue to supply these services?' In other words, how much of the world's species diversity is redundant? Would a 'weedy' world (see 5.2.3) from which most species diversity had been lost remain hospitable to humanity? If not, where on the continuum between today's species richness and a species-poor planet would one expect a serious deterioration of services? It is clear that many ecosystem services are already faltering: maintenance of the mix of gases in the atmosphere is an obvious example. Deforestation is partially responsible, and is associated with major losses of species diversity. In this case, however, as in most others, it is not possible to determine the degree to which species loss will impair the services in the long term. One can imagine polycultures substituted for natural forests that would sequester carbon, reduce nitrous oxide fluxes and otherwise help stabilize atmospheric composition. Similarly, ice plant (*Mesembryanthemum crystallinum*) and Bermuda grass (*Cynodon dactylon*) might hold soils in place in many parts of the world as thoroughly as species-rich mixes of native plants. Eucalyptus trees transpire, break the force of rain, protect soils, and thus contribute to regular flows of fresh water in California – possibly just as well as native live oaks. They also can provide the shade and wind-screening functions of a diversity of indigenous trees. It may be that most species are redundant from the viewpoint of ecosystem services, as suggested by Walker (1992) and developed further by Lawton and Brown (1993) – the so-called 'redundant species hypothesis' (see further discussion in 5.2.2). Even looking at the short term, it seems unlikely, however, that this is the case (e.g. Naeem *et al.* 1994).

The ability of a monoculture to maintain services becomes more problematical if the longer term is considered. A monoculture of a tree species may provide

many ecosystem services for decades or even a few centuries, but it may be more vulnerable to catastrophic disease and/or be less resilient in the face of environmental change than would a natural forest with its original tree species diversity. The presence of many species would generally increase the chance that, if rapid change exterminated some species, there would be ecological equivalents present, more tolerant to the particular change and able to take over their roles. Furthermore, a drastic reduction in species diversity in an ecosystem may lead to sequences of community development whose direction and consequences for ecosystem services may be very difficult to predict (e.g. Drake *et al.* 1993; Hughes 1994; Luh and Pimm 1993).

If the tree monoculture were genetically uniform, the ecosystem services it supplied would be even more vulnerable to disruption. A natural forest often contains a diversity of populations of component tree species – populations adapted to different environmental regimes (say, north- and south-facing slopes). They would contain interpopulation genetic variation which could be crucial to the ability of species to evolve in response to rapid changes in environmental conditions, such as climatic shifts due to global warming.

From a very broad perspective, the redundant species hypothesis seems even less likely to be correct. While a 'weedy' ecosystem might satisfactorily maintain the gaseous mix of the atmosphere, control erosion, conserve water flows, and so on, other services seem almost certain to be less secure than in a diverse natural system. A tree farm might not shelter the diversity of natural enemies of crop pests that would be found in a natural forest. For example, avian diversity is correlated with structural diversity in forests, and many bird species have habitat requirements not met in even aged stands of monocultures. In addition, a tree farm may be less effective than a mix of native species at recycling nutrients and maintaining a fertile soil (Aber and Melillo 1991).

Of course, it is difficult to predict the need for pest control services in a highly biologically depauperate world, although simple food-chain considerations would suggest that herbivorous pests would be more likely than their predacious enemies to persist in such an environment. Ecologists know that extinction of species will not necessarily cause deterioration of certain ecosystem services – that there is some redundancy at least in the short term since observed extinctions do not always cause detectable impacts on services. However, ecologists cannot determine the actual degree of redundancy present, nor whether short-term redundancy holds for the long term.

There are, of course, some ecosystem services that automatically would be compromised by losses of species, populations and genetic diversity. Direct provision of food and maintenance of the genetic library are the best

examples. Loss of fisheries or game species can more or less permanently remove a substantial source of human food – as did the extermination of the passenger pigeon (Blockstein and Tordoff 1985). The extinction of one species often leads to the extinction of others, which often are directly (as in the case of monophagous herbivores and parasites) or indirectly (e.g. Paine 1966; Gilbert 1980; Daily *et al.* 1993) dependent on the organism that has disappeared. Thus, while loss of any species or genetically distinct population by definition depletes the genetic library (and thus its potential for supplying direct economic benefits to society), each extinction also has the potential for generating cascades of further losses. Therefore, conservation efforts should focus not only on species, but also on ecological and evolutionary processes which occur in the matrix of the community and ecosystem (see also Section 4.5).

Given such examples, it would be prudent to assume that ecosystem services depend significantly on species diversity, and more heavily on population diversity (Ehrlich and Daily 1993; Daily and Ehrlich 1994), since on local, regional and global scales, ecosystem services are delivered by populations. Multitudinous populations of plants, animals and microorganisms, each usually genetically adapted to a relatively narrow range of environmental conditions, are necessary to maintain ecosystem functioning. After all, very few organisms of any functional group can thrive under a wide variety of physical and biotic conditions: adaptation to local circumstance is nearly ubiquitous. Much too little attention has been paid to the connection between the diversity of populations (both Mendelian populations and demographic units) and the delivery of ecosystem services.

The uncertainties of the relationship between species diversity and ecosystem services led more than a decade ago to the formulation of the ‘rivet hypothesis’ (Ehrlich and Ehrlich 1981). It says, in essence, that given the complexity of ecosystems and our lack of detailed knowledge of their functioning (especially in the long term), it is foolish to remove species randomly just as it would be foolish to pop rivets from an airplane’s wing. There are more rivets in an airplane’s wing than are necessary for its integrity, but removing too many can cause a structural disaster. At some point, removing one more rivet will cause others to pop out and the wing to fail. While there is at least some redundancy in the role of species in delivering services, there may also be extinction thresholds. For instance, if a ‘keystone’ species (see 5.2.2) is extirpated, it could lead to an extinction cascade that would eliminate a series of functionally related species and lead to unacceptable deterioration of an ecosystem service. Or, the removal of one or a few predatory species can lead to serious outbreaks of pest species. This is demonstrated by a well-

documented set of examples of the problem of ‘promotion’ of previously harmless organisms to the status of agricultural pests when natural predators have been reduced or eliminated from a system by misuse of pesticides (e.g. Barducci 1972).

There are, of course, costs involved in making an airplane wing safer. Strengthening the structure usually means adding more weight, which in turn means that less fuel or fewer passengers can be carried. A 747 that carried only one passenger could be made very safe indeed, but would be totally uneconomical. There are both costs and benefits of safety in airliners, and where the balance is struck is largely a social and economic decision.

The same is true for the preservation of biodiversity. About 11% of Earth’s land surface is now covered by crops, rather than more diverse ecosystems, and attempts to provide food for a human population that may more than double in the next century is likely to lead to further conversion to agriculture of relatively natural ecosystems. Diverse systems seem doomed to diminish as a result of increasing urbanization, grazing pressure, and other consequences of the expanding scale of the human enterprise. Because of human needs (and greed), the costs of preserving diversity seem bound to increase rapidly, but simultaneously the costs to civilization of destroying it may escalate as well.

It remains a major challenge to ecologists to improve their understanding of the relationship between biodiversity and ecosystem functioning so they can better predict where the increasing risks of destroying biodiversity become greater than the increasing costs of preserving it. At the moment, about all that can be said is that until and unless it can be definitively shown that the rivet hypothesis is over-conservative, it would be folly for humanity to continue to wipe out species diversity indiscriminately. Further deliberate destruction of biodiversity at the genetic, population, species or ecosystem level should be permitted only as a last resort, when crucial human needs can be met in no other way. The burden of proof of need must rest on those proposing the destruction, and societies must guard against short-term financial gain at the expense of the majority.

On the basis of present knowledge, we cannot safely assume that a ‘weedy world’ will support the human enterprise as effectively or for as long as one rich in organisms that are not human inquilines. Until and unless further research clearly shows how diversity can safely be reduced, we must act as if all levels of diversity will be essential if ecosystems are to respond to the rapid and unprecedented environmental changes that now face human society. And even if ecologists show that ‘weedy’ species are all we need to supply basic services to humanity, they cannot show that the ethical and aesthetic arguments for

maximizing the preservation of biodiversity are incorrect. They lie outside realm of science, but contain some of the most powerful reasons for saving our only known living companions in the universe.

5.2 Functional properties of biodiversity: a hierarchical perspective

5.2.1 Genetic diversity and ecosystem functioning

In order to evaluate the significance of genetic diversity in ecosystem functioning, the role of the individual must first be appreciated. Individuals – not species – eat or are eaten, live or die, capture energy and transfer energy. Species do not interact: individuals of different species interact. Communities are not assemblages of species: they are assemblages of individuals of the same and different species. All too often in the ecological literature, species are treated as monolithic, static entities that are the basic building blocks of communities and ecosystems. Fortunately, a new, individual-based ecology is emerging (Hogeweg and Hesper 1990; Rose *et al.* 1993), and as it matures and develops, the role of individuals in ecological processes will undoubtedly gain a deeper appreciation. Much of the individual variation observed at the intraspecific level is due for example to the individual's sex, age or past interactions with the environment. However, one class of intraspecific variation – genetic variation – plays a particularly important role in processes above the individual level and this subsection will deal only with this genetic component of individual variation.

Genetic variation ties together the biological properties of the individual and the biological properties of the species. DNA, the material basis of genetic variation, can replicate and be passed on to future generations and to more than one individual. Accordingly, genetic variation has an existence in space and time that transcends the individual. This temporal and spatial existence of genetic variation provides both the raw material and the physical continuity for the process of evolution at the species level. This capacity to evolve provides insurance against future environmental changes. Therefore, the emergent population property of evolution augments – not diminishes – the importance of genetic diversity among individuals.

The above does not imply that species are not important in ecology or that they are not real biological units (Templeton 1989). Adaptation is one of the most important evolutionary processes that emerge at the population level. Through adaptation, individuals within a species come to have traits that help in their survival and reproduction with regard to both their physical and biotic environments. These adaptations result in an ecological distinctiveness that emerges at the species level that has been described as the 'keystone of evolution' because it serves as the basis of diversification of the organic world, adaptive radiation and evolutionary progress (Mayr 1970). Ecosystems function by a variety of processes that are shaped by adaptive evolution. They first require that energy be captured from the physical environment and be transferred into the biological realm in the form of biomass. The amount of physical energy that is converted into biomass is influenced

by the genotype of the individual, as evidenced by the fact that genetic variation among individuals is the basis of much of the improvement in biomass productivity of modern crop plants (Oldfield 1984). The genetic improvement of domesticated animal stocks also shows that the efficiency of energy transfer from one trophic level to the next is another genetically variable trait (Oldfield 1984), and indeed genetic variation of the proportion of ingested energy that is converted into biomass exists within our own species (Reilly *et al.* 1992).

The transfer of energy from one trophic level to the next is mediated by interactions among individuals, including individuals of different species. Many other types of inter-'specific' interactions are critical for ecosystem functioning, including competitive and mutualistic interactions. These interactions are shaped by adaptive processes working upon intraspecific genetic variability, as illustrated by the extensive literature on coevolution (Pirozynski and Hawksworth 1988; Thompson 1988; Mitter *et al.* 1991; Fritz and Simms 1992; Jolivet 1992; see Section 4.5), the evolution of human diseases (Ewald 1994), and the human evolutionary responses to these diseases (Weiss 1993). These biotic interactions shape the structure and the functioning of the biological community component of ecosystems. Although described as 'interspecific', these interactions are sometimes best understood at the level of intraspecific genetic variation. For example, in *Heliconius* butterflies the genetic system controlling adult wing pattern evolves as an intra- and interspecific mutualism (to provide a common inter/intraspecific signal of distastefulness to potential predators), while the genetic system controlling adult foraging behaviour evolves through intra- and interspecific competition for scarce pollen resources (Templeton and Gilbert 1985). Thus, species and even individuals cannot be said to have *an* interaction in this example. Rather, the community structure in this case can only be understood at the level of genetic traits within individuals (Templeton and Gilbert 1985).

Finally, ecosystem functioning requires interactions of individuals with the physical environment, and as with biotic interactions, these are shaped by adaptive evolution operating upon individual genetic variation. This includes adaptation to the geological/chemical environment (Ware 1990; Ware and Pinion 1990) and to physical stresses such as desiccation (Templeton *et al.* 1989) or flooding (Schwartz 1969).

As discussed above, genetic diversity as shaped by adaptive evolution underlies ecological processes at the population, species, community and ecosystem levels. Genetic diversity itself has a variety of meanings and levels of measurement (Templeton 1994; see also Section 2.2), the most basic being allelic diversity (alternative forms of genes at the same locus). Allelic diversity is created by the

process of mutation and can subsequently be lost during the evolutionary process, either at random (genetic drift in the species as a whole), or due to natural selection (elimination of deleterious alleles and fixation of favourable alleles). The amount of allelic diversity in a species represents a dynamic balance between these processes.

Species exist in both space and time, and so does intraspecific allelic diversity. In some species, the allelic diversity is widely and nearly uniformly distributed across a species' geographical range (Barrowclough 1983). At the other extreme are species in which local populations have little or no allelic diversity, although different local populations can be fixed for alternative alleles (Templeton *et al.* 1990). The forces that partition and create genetic hierarchies within a species include such factors as the system of mating, genetic drift, population subdivision, dispersal and gene flow (see Section 4.2). The partitioning of allelic diversity within and among local breeding populations is primarily due to the dynamic balance between local genetic drift (which causes the local breeding population to lose allelic diversity but causes an increase in among-population genetic differentiation) versus gene flow or dispersal (which brings new allelic diversity into the local population and reduces genetic differentiation among populations). In sexually reproducing populations, the allelic diversity within a local population is amplified into vast numbers of combinations of genotypic diversity through the mechanisms of gamete formation and union (system of mating). This determines the extent to which diploid individuals will themselves carry allelic diversity in the form of heterozygosity (an individual carrying two different alleles at a locus).

What is the significance of genetic diversity at these various intraspecific levels? Starting at the individual level in sexual populations, attention has focused on the importance of heterozygosity (see also Section 4.2). Several studies have concluded that as heterozygosity increases, individual fitness or fitness correlates also increase (Clarke 1993). Unfortunately, due to confounding factors, there is little convincing evidence for heterozygote superiority as a general phenomenon (Clarke 1993) or as a quantitatively important explanation of inbreeding depression (a loss of fitness in the offspring of matings between close biological relatives) (Templeton 1987). This is not to say that heterozygote superiority does not occur (for an example, see Templeton 1982); only that it is not universal. Plants and animals adapt to their system of mating, and if they have a system of mating that favours homozygosity, alleles with high fitness under homozygosity are favoured by natural selection (Templeton 1982). Because there is much diversity in systems of mating across species (from panmixia to selfing), heterozygosity may be important in some species and irrelevant in others. Heterozygosity is certainly irrelevant in

the vast numbers of haploid individuals that dominate the microbial world and commonly represent critical components of ecosystem functioning.

Studies on fitness and heterozygosity, and on inbreeding depression, do reveal one common theme – the importance of multilocus combinations in individual fitness (Templeton and Read 1984, 1994; Clarke 1993). Despite the fact that there is more consistent evidence for epistasis (multilocus interactions) leading to co-adapted gene complexes being more important than heterozygosity in determining individual fitness (Clarke 1993) and that epistasis is important for individual fitness in the haploid, microbial world as well (Lenski 1988a, b), combinatorial genetic diversity has been explicitly incorporated into only a handful of conservation programmes (e.g. Templeton and Read 1984, 1994; Emlen 1991).

At the level of a local population, genetic variation exists in the form of allelic and combinatorial diversity in the local population's gene pool. Concern about variation within local populations has focused on two issues: (1) the fear that genetic uniformity makes populations more susceptible to pests or disease pathogens (O'Brien *et al.* 1985; Potts and Wakeland 1993), and (2) the fear that loss of genetic diversity at this level will reduce a population's ability to respond to environmental change (both biotic and abiotic) through the process of adaptation via natural selection. Recently, Caro and Laurenson (1994) questioned the importance of genetic variation with respect to evidence for increased risk to short-term population extinction. The cases of increased susceptibility to pathogens in natural populations that are low in genetic variation are not definite proofs of the importance of genetic variation but are consistent with this conclusion (O'Brien *et al.* 1985; Moritz *et al.* 1991). Moreover, there is a rich agricultural literature on the dangers of genetic monocultures with respect to pathogens (Bishop and Cook 1981; Oldfield 1984; Browning 1991). Accordingly, it would be foolish to dismiss this role of genetic variation in mediating the intensity and ecological consequences of host/pathogen interactions. The necessity of genetic diversity for adaptive evolution is well established both theoretically (Templeton 1982) and experimentally (e.g. Carson 1961). There are also abundant natural examples of organisms utilizing their genetic diversity to adapt to environmental change, including human-induced environmental change (Bishop and Cook 1981). These adaptations can directly affect an organism's niche and biotic interactions in the community (Singer *et al.* 1993). For example Sork *et al.* (1993) have found that the northern red oaks in the Ozarks adapt very finely to variations in interactions with herbivores and to the physical environment. These examples illustrate the importance of genetic diversity as a component of adaptive evolution. Because adaptive flexibility is only realized in evolutionary time, the criterion of short-term extinction risk

(Caro and Laurenson 1994) is inherently inappropriate for assessing the importance of genetic diversity with respect to adaptation. The real danger from loss of genetic variation is the concomitant loss of adaptive flexibility in the face of changing environments, which reduces the long-term probability of persistence of the population.

Finally, genetic diversity exists as differences among local populations, with among-population differentiation tending to increase with decreasing gene flow in sexual populations and decreasing dispersal in asexual populations (see Section 3.1). This spatial component of genetic diversity augments the likelihood and accuracy of adaptation to local environments (Bishop *et al.* 1978; Templeton *et al.* 1989) and response to environmental change (Lynch and Lande 1993). As a result of local adaptation, different local populations of a species cannot be regarded as interchangeable (Powers *et al.* 1991; Watt 1991). One consequence of local adaptation is the expectation that reintroduction programmes will have increasing chances of success with increasing geographical proximity of the site of origin of the propagules to the site of release, as indeed has been repeatedly observed (Greig 1979; Griffith *et al.* 1989). In addition, genetic diversity has several direct implications for the relationship between biodiversity (at the intraspecific level in this case) and ecosystem services. Two representative examples are: (1) the maintenance of adaptive flexibility – an important component in recovery from disturbance and (2) the introduction of slash-and-burn agriculture which increased malaria in tropical Africa which in turn affected the incidence of sickle cell anaemia there (see Templeton 1982).

In summary, genetic diversity has many manifestations and plays many biologically significant roles within a species. This significance does not stop at the species boundary; rather, primarily through the intraspecific genetic process of adaptation, genetic diversity influences the emergence and functioning of higher order, ecological, systems.

5.2.2 Biodiversity effects on patterns and processes of communities and ecosystems

5.2.2.1 Introduction

The loss of species through changes in land-use has occurred frequently and is irrevocable (Solbrig 1991; NRC 1995). Reductions in population size, fragmentation of populations, and alterations in the relative abundance of species are increasingly common phenomena with profound ecological implications (5.2.3). Human introduction of new species into natural communities is also common, and often has profound ecological effects (Drake *et al.* 1989; Vitousek 1990; Carpenter *et al.* 1992; D'Antonio and Vitousek 1992; Carleton and Geller 1993; Huston 1994). How do these changes in diversity affect ecological communities and ecosystems? Can the consequences of deletions or additions be predicted? What patterns are emerging from the plethora of investigations into these complex phenomena?

During recent decades, several hypotheses have arisen to describe the observed or expected consequences of the addition or removal of species. These hypotheses are based in part on observations following species reductions, deletions or additions and in part on predictions from ecological modelling and theory. These hypotheses are often cast as alternatives, but often focus on different aspects of the topic. Some hypotheses emphasize the number of species in the community (Vitousek and Hooper 1993), others the degree of similarity among species in traits that affect community or ecosystem functioning (Menge *et al.* 1986; Walker 1992; Lawton and Brown 1993; Frost *et al.* 1995; Sala *et al.* 1996). Here, we briefly review some of these hypotheses, then present an emerging conceptual framework that integrates and synthesizes the disparate approaches. In reviewing the key ideas, we delineate the hypotheses that centre on the notion of functional similarity among species, suggest how these hypotheses relate to one another, and point out how a number of them have evolved as additional information and understanding have emerged.

5.2.2.2 Relationship between species and the functioning of ecological communities and ecosystems: hypotheses concerning similarity among species

Several hypotheses about changes in species diversity and community or ecosystem responses consider the functional similarity among species, in other words, how similar different species are to one another with respect to their roles in community or ecosystem processes. The different approaches may be viewed as lying along a continuum. At one extreme is the idea that each species is unique and important, such that its removal or loss will have demonstrable consequences to the functioning of the community or ecosystem. At the other end of the spectrum is the notion that species overlap in function to a sufficient degree that removal or loss of a species will be compensated by others, with negligible overall consequences to the community or ecosystem. In the middle of this continuum lies a mixed community, with some unique species and others with substantial overlap in functional properties.

One of the first attempts to address this similarity among species was the notion of 'keystone species' codified by Paine (1969). The central core of the keystone concept is that only one or a few species have uniquely important effects on the community or ecosystem by virtue of unique traits or attributes. Analogous to the removal of a keystone from an arch, removal of a keystone species results in dramatic changes in the functional properties of the ecological system (e.g. changes in diversity, abundance, habitat structure). Paine initially restricted the concept of keystone species to predators of competitive dominants in a community. Building on a series of investigations in a wide range of ecosystems, a recent review (Power and Mills 1995) expands the keystone concept to include any species with an impact on its community or ecosystem that is disproportionately large relative to the abundance of the species (Box 5.2-1). Their review concludes that (a) keystone species have been demonstrated in a wide variety of ecosystems, (b) based on indirect evidence, keystones may be more prevalent than has been demonstrated, and (c) the concept can apply to individual species or groups of species, but that (d) *a priori* prediction of a keystone species remains elusive.

At one end of the continuum of similarity among species lies the hypothesis that species overlap with one another in functional properties to a sufficient degree that loss of any one species has negligible effect. This hypothesis has been termed the redundancy hypothesis (Walker 1992; Lawton and Brown 1993) but others suggest that the term 'functional compensation' hypothesis is preferable (Menge *et al.* 1994; Frost *et al.* 1995). The far opposite end of the hypothetical continuum in similarity is suggested primarily for heuristic purposes. There is no evidence that each and every species plays a unique role such that its absence

Box 5.2-1: Keystone species – what are they and why do they matter?

A keystone species is a species whose impacts on its community or ecosystem are large and greater than would be expected from its relative abundance. This definition is unconstrained by a species’ trophic status, mode of impact, or nature of community or ecosystem response. For any species, a relationship exists between the proportional abundance of that species and its total impact on the community or ecosystem. Proportional abundance is normally measured in units of biomass (see graph below). Species whose total impact scales exactly to their proportional abundance fall on the diagonal line ($X = Y$). keystones, in contrast, have total effects that greatly exceed this line of proportional equality. Very rare species with total impacts that exceed the diagonal, but are nonetheless relatively small, are not considered keystones, since their overall effect is minimal. For instance, a very rare rhinovirus that makes a wildebeest sneeze (V_R) might have a total effect far exceeding that expected from its biomass. However, the rhinovirus would not qualify as a keystone species because of its low absolute total effect.

By contrast, an equally rare distemper virus (V_D) that kills lions or wild dogs might have a total impact of sufficient magnitude for keystone designation. The keystone species illustrated in the figure include the sea star *Pisaster* (P), the predatory whelk *Concholepas* (C), sea otters (O), and freshwater bass (B). All are species whose total impact is large and large relative to their abundance. By contrast trees (T), giant kelp (K), prairie grass (G) and reef-building corals (Cr) which dominate community biomass also have total impacts that are large, but not disproportionate to their biomass. These non-keystone dominants are to the right of the line.

Keystone species are usually detected when they are removed or disappear from a system. In the cases illustrated, the absence of the keystone species resulted in dramatic changes to the rest of the community (Box 6.1-1 provides details on the otter example). Keystone species have been reported from a wide variety of ecosystems, all trophic levels and many taxa. Their pivotal impact is often not appreciated until they are absent.

Total (collective) impact of a species (absolute value of community impact \times proportional abundance) of species versus their proportional abundance. Points representing a species whose total impact is proportional to its abundance would fall along the diagonal line ($X = Y$). Keystones are species whose effects exceed their proportional abundances by some large factor and whose total effect exceeds some threshold. Dominants are species which dominate community biomass and whose ecosystem impacts are large, but not disproportionate to their biomass. Letters represent examples of particular species described in the text (Power and Mills 1995).

would immediately result in a dramatic change in the functioning of the ecological system.

Another hypothesis concerning functional consequences of loss of species is the ‘rivet hypothesis’. As originally formulated (Ehrlich and Ehrlich 1981), this hypothesis suggested that each species is like a rivet in an aircraft such that each species loss contributes equally to the probability of large changes in community and ecosystem processes. This hypothesis, too, has evolved and now (Chapter 5.1) suggests that, like rivets in critical places in an aircraft, certain species may play more critical roles than others. A number of features are essential to this hypothesis: the number of rivets (= species), their placement, and their immediate neighbours.

5.2.2.3 Key concepts and terms

Consideration of the relationship between species diversity and the functioning of communities and ecosystems requires a clear description of the important terms, e.g. **functional group**, **community patterns**, **community processes**, **ecosystem patterns** and **ecosystem processes**, as given below.

There is no intrinsically unique level at which biotic diversity affects ecosystem processes. The current level of conceptual understanding of the effects of biodiversity on ecosystem processes is so primitive that it is easiest to recognize these linkages at the level of **functional groups**, i.e. groups of species that have ecologically similar effects on ecosystem processes (Woodward 1987; Chapin 1993; Huston 1994). However, no two species or individuals are ecologically identical, so as our understanding improves we expect to recognize situations where species diversity within functional groups (Huston 1994; Cushman 1995) or genetic diversity within species (5.2.1) has important ecosystem consequences. Moreover, because most species belong to more than one functional group and affect species belonging to other functional groups, prediction of the overall consequences of a deletion or addition is complex. For example, large kelps provide the physical structure of a kelp forest in addition to providing a substantial portion of the primary production. Other macrophytes such as algal crusts or turfs and phytoplankton could compensate in part for the loss of production by kelps if kelps were deleted from the system, but would not provide the three-dimensional habitat for a diverse assemblage of invertebrates, juvenile and adult fishes, and marine mammals. Thus compensation by other members in one functional group is not automatically linked to compensation in other functions.

The **community processes** we consider here are species interactions (e.g. competition, predation, mutualism), which we distinguish from **ecosystem processes** — the flows of water, energy, and materials within and among ecosystems (e.g. primary production, microbial

immobilization, nutrient leaching). **Community patterns** are described in terms of the abundance and spatial distribution of species in an ecosystem, whereas **ecosystem patterns** are the quantities and configuration of water, energy and materials in biotic and abiotic components of the system. The same organisms carry out both community and ecosystem processes, so these and other levels of organization are closely linked. For example, introduction of a disease that alters the abundance of a flammable grass (a community change) may depend on genetic variability in disease resistance (genetic diversity) and may alter fire frequency and stand biomass (an ecosystem trait) and the propagation of fire among ecosystems in a watershed (a landscape process).

5.2.2.4 Integrated framework

Here we present a general framework, based on the hypotheses described above, for the information needed to predict the functional consequences of changes in diversity. To understand the community and ecosystem consequences of a species invasion or extinction, we must know at least (1) the approximate number of species in the community, (2) the relative abundance of these species, (3) how strongly a given species differs from other species in the community, (4) the impact of particular species traits on community and ecosystem processes and (5) the indirect effects that a species has on other species in the community. We refer to these as ‘critical components of diversity’.

1. The number of species in an ecosystem (species richness) undoubtedly influences some community and ecosystem processes, but we do not know (a) the shape of the relationship between species number and the rate of an ecosystem process or (b) where this relationship saturates (Vitousek and Hooper 1993) (Figure 5.2-1a). If the relationship saturates, and we consider only species richness, we expect species additions or deletions to have their greatest effect when there are relatively few species in the community, as on islands (Cushman 1995).
2. The most abundant species of a community in terms of biomass typically accounts for the greatest proportion of productivity and nutrient cycling (Bormann and Likens 1979; Valiela 1984). Thus, we expect deletion of community dominants to have greater impact on some ecosystem processes than will deletion of species that are small and/or rare (Cushman 1995; Sala *et al.* 1996) (Figure 5.2-1b).
3. The impact of the addition or deletion of a particular species depends on its degree of functional similarity to other species in the community. If a species is

Figure 5.2-1: Some possible effects on ecosystem processes of (a) altering the number of species (ignoring relative abundance and traits of species; Vitousek and Hooper 1993); (b) deleting rare vs dominant species (Sala *et al.* 1996); (c) deleting keystone vs compensating species. The effect of number of species (a) depends on whether changes in ecosystem processes are equally affected by each species addition (Type 1), saturate with addition of new species (Type 2), or have an abrupt threshold with species diversity having no effect on ecosystem processes (Type 3). In (b) and (c), we assume a saturating relationship between ecosystem processes and species number. Arrows indicate the direction of change in ecosystem processes with deletion of species.

functionally similar to other species in the community (i.e. belongs to the same functional group) (Menge *et al.* 1986; Frost *et al.* 1995; Smith *et al.* 1995), its addition or deletion may have less effect than if the species has traits that uniquely affect community or ecosystem processes.

4. Certain traits of organisms have greater ecosystem impacts than other traits. Vitousek (1990) and Chapin *et al.* (1996) suggest that species modify ecosystem processes primarily through their effects on (1) availability of resources in the environment, (2) rates of consumption of resources or prey, and (3) the disturbance regime. In this section we summarize the general reasons for ecosystem sensitivity to changes in these categories of species effects. If a species is unique in the species or resources it consumes or controls (as often occurs at high trophic levels: top-down controls) or affects soil resource pools and supply rates (bottom-up controls, e.g. nitrogen fixation, hydraulic lift, litter quality) or disturbance frequency and intensity (the relative importance of equilibrium and non-equilibrium processes, e.g. digging and burrowing by animals, flammability in plants), gain or loss of such species is likely to have large *amplifying* effects on both community and ecosystem processes. These are the traits most likely to characterize keystone species. By contrast, if species are near the base of the food chain and are similar to other species in their resource (food) requirements, the addition or deletion of a

species generally has a small effect on ecosystem processes because of competitive interactions and *compensatory* responses by the existing or remaining species (Frost *et al.* 1995; Chapin *et al.* 1996). These compensatory changes alter community composition and diversity, but have minor effects on the quantity of resources consumed by the trophic level as a whole (Figure 5.2-1c).

5. Species which themselves have small effects on ecosystem processes can have large indirect effects if they influence the abundance of other species with large direct ecosystem effects. For example, a seed disperser or pollinator that has little direct effect on ecosystem processes may be essential for the persistence of a canopy species with greater direct ecosystem impact (Gilbert 1980; Paine 1980; Cushman 1995).

None of these criteria, taken singly, allow us to predict the community or ecosystem consequences of changes in diversity. However, taken together, these critical components of diversity determine the ecosystem consequences of addition or deletion of species from a community.

5.2.2.5 Effects of diversity per se on ecosystem processes

Species number (the first critical component of diversity) is functionally important because it (1) increases the rate or

efficiency of resource capture under steady-state conditions and (2) provides insurance against large changes in ecosystem processes in response to disturbance or environmental change. When species diversity is extremely low (e.g. a crop monoculture), total nutrient uptake and productivity of a crop, and its consumption by higher trophic levels, is often less than in more complex ecosystems (Swift and Anderson 1993; Vitousek and Hooper 1993; Naeem *et al.* 1994), although forests dominated by a single tree species are not notably less productive than highly diverse forests (Rodin and Bazilevich 1967). In artificial tropical communities, a variety of biogeochemical processes differed strikingly between plots with 0, 1, and 100 species but not among highly diverse plots of differing species composition (Ewel *et al.* 1991; Vitousek and Hooper 1993). Thus, we know that species diversity affects ecosystem processes somewhere between 1 and 100 species, but we do not know where this relationship saturates (Figure 5.2-1a). Artificial communities with differing numbers (1–4) of species per trophic level also differed in productivity (Naeem *et al.* 1994). The challenge in experimental studies is to separate the effects of species number from the effects of the traits of the component species. This is an important area for future research.

Species number is also important because it provides insurance against change in function in the event that a species is lost from an ecosystem. Because each species shows a unique response to climate and resources (Whittaker 1975; McNaughton 1977; Chapin and Shaver 1985), any change in climate or climatic extremes that is severe enough to cause extinction of one species is less likely to eliminate all members from a functional group. For example, Tilman and Downing (1994) showed that, due to the presence of drought-tolerant species, diverse grasslands maintain higher productivity in response to drought than do grasslands whose diversity has been reduced by experimental nutrient addition (see Section 6.1.7.3 and Figure 6.1-3). Conversely, the fewer species there are in a functional group or group of interacting species (e.g. pollinators), the more likely it is that any extinction event or series of such events will alter the ecosystem processes associated with that functional group (Holling 1986; Chapin *et al.* 1996). Thus, genetic and species diversity *per se* is important to the long-term maintenance of community and ecosystem structure and processes. This argues that no two species are ecologically redundant, even if they are similar in their ecosystem effects under a particular set of environmental circumstances.

It is intriguing to ask whether the hierarchical level at which diversity is expressed contributes significantly to the stability of ecosystem processes. Marine ecosystems may have a particularly broad range of physiological and genetic diversity because their diversity occurs at a higher

taxonomic level than in terrestrial systems. For example, 32 of the 33 extant animal phyla occur in the sea (Margulis and Schwartz 1988, Norse 1993) and exhibit a wide array of body plans, compared to the 17 phyla on land. We do not know whether this hierarchical level at which diversity is expressed contributes significantly to the environmental tolerance of ecosystem processes.

Species diversity is important to the maintenance of ecosystem processes over a complete cycle of common disturbance events. Following disturbance, initial colonization by early successional species often stabilizes the substrate, retains nutrients which are later used by other species, or retains moisture which facilitates colonization by less tolerant species. For example, riparian shrubs can stabilize stream banks sufficiently to allow colonization by forest trees (van Cleve *et al.* 1991). Rapid colonization by early successional species following fire or forest cutting retains nutrients which, in the long term, support the growth of late-successional forests (Stark and Steele 1977; Bormann and Likens 1979). The long-term stability and resilience of communities and ecosystems, therefore, probably requires a diversity of species whose ecosystem impact is minimal at most times but critical at certain phases of succession.

5.2.2.6 Mechanisms of community and ecosystem change due to species traits

Species often differ strikingly within and between communities in properties that affect community and ecosystem patterns and processes (Hobbie 1992, Wilson and Agnew 1992, Chapin 1993; van Breemen 1993; Paine 1994). Here we summarize the general reasons for ecosystem sensitivity to the fourth critical component of diversity, i.e. species traits that influence resource availability, resource consumption or disturbance.

(1) Ecosystem processes are highly sensitive to changes in species that influence the *supply* or *turnover rates* of water, nutrients or space. The supply of soil resources is an important 'bottom-up' control of terrestrial ecosystem processes (Jenny 1980). Similarly, nutrients are critical ecosystem controls in fresh water (Schindler 1978; Carpenter and Kitchell 1993) and in open and coastal marine ecosystems (Lobban and Harrison 1994; Menge *et al.* 1995). Space is a limiting resource in rocky intertidal communities (Dayton 1971; Connell 1978; Paine 1994). Many of the traits that influence resource supply tend to have highly skewed or discontinuous distributions among species in the community, so that a few species tend to have values for the trait that are quite different from those of other species in the community (Figure 5.2-1b,c). Introduction of exotic species with symbiotic nitrogen fixation in Hawaii greatly increased productivity and nitrogen cycling and altered the structure and species

Figure 5.2-2: Typical frequency of occurrence of (a) continuously varying traits, (b) discrete traits, and (c) traits with skewed distribution among species in a community (Chapin *et al.* 1996).

composition of forests (Vitousek *et al.* 1987). Nepalese alder (*Alnus*) increases nitrogen inputs, and bamboo retains newly weathered potassium in Asian slash-and-burn agriculture (Ramakrishnan 1992). Each of the species in these examples differs strongly from other species in the community in its effects on nutrient supply. Similarly, introduction of deep-rooted species, such as *Eucalyptus* or *Tamarix*, can increase access to water and nutrients (van Hylckama 1974), thereby increasing the pool of resources available to support ecosystem productivity (Robles and Chapin 1996). These differences in rooting depth can be important at the regional scale. Simulations suggest that conversion of the Amazon Basin from forest to pasture would cause a permanent warming and drying of South America because the shallower roots of grasses would lead to reduced evapotranspiration and greater dissipation of energy as sensible heat (Shukla *et al.* 1990).

Animals can influence the resource base of the ecosystem by transporting nutrients among microsites within an ecosystem (e.g. concentration of nutrients in polygon troughs by lemmings (Batzli *et al.* 1980), on hilltops by sheep, or beneath desert shrubs by rodents) or by importing nutrients to oligotrophic ecosystems (e.g. nutrient movement from oceans to streams by migratory

salmon or transport of copepod fecal pellets to the deep sea). Species differences in soil microbial communities determine rates of nitrification, denitrification and methanogenesis and, consequently, the loss of trace gases to the atmosphere. Rates of nitrification also influence the susceptibility of N to loss by leaching or denitrification on land. Because these processes are controlled by relatively few species of microorganisms, i.e. the traits are uncommon and discontinuous, changes in their abundance could have large effects on N loss from ecosystems (Frost *et al.* 1995; Schimel 1995).

In terrestrial ecosystems, species also affect the resource supply rate through their influence on the turnover of nutrients in soils. Differences in tissue quality are critical controls over litter decomposition (Melillo *et al.* 1982; Flanagan and van Cleve 1983; Berg and McClaugherty 1989). Litter from low-resource plants decomposes slowly because of the negative effect on soil microbes of lignin, tannins, waxes and other recalcitrant or toxic compounds, reinforcing the low nutrient availability of these sites (Chapin 1991; Hobbie 1992). By contrast, species from high-resource sites produce rapidly decomposing litter with more N and P (Vitousek 1982) and *less* recalcitrant compounds. Thus, invasion or extinction of a species that differs substantially in litter quality from other species in the community could profoundly alter ecosystem processes. Long-term field experiments suggest that the nutrient content of litter is more important than carbon quality in exerting these ecosystem effects (Berendse *et al.* 1994). Because of the continuous variation in litter nutrient concentration among species (Chapin and Kedrowski 1983), litter-quality effects on ecosystem processes are probably a continuous function of plant traits. Plants can also alter nutrient supply rates through their effects on soil acidity, which is largely a function of the carbon quality of the litter and of the preferred form in which nitrogen is absorbed from the soil (Bormann and Likens 1979). Plants *indirectly* influence rates of nutrient supply through modification of the micro-environment (Wilson and Agnew 1992; Hobbie 1995). For example, arctic mosses, with their low rates of evapotranspiration (leading to water-logging) and effective insulation (preventing soil warming) indirectly inhibit decomposition (Gorham 1991). These species-specific effects could be important in determining both the pools of resources available to plants and higher trophic levels, and the rate at which these pools turn over.

Species traits that alter the resource supply have just as strong an effect on community processes as on ecosystem processes because resource supply and the balance of available resources determine the competitive balance among species in the community (Berendse *et al.* 1987; Tilman 1988; Aerts and van der Peijl 1993). In rocky intertidal communities, predation and herbivory on species that monopolize space play key roles in determining

community patterns and processes. By preventing mussels from dominating mid and lower shore levels, seastars on the northeastern Pacific and eastern Tasman shores, and snails on southeastern Pacific shores, make space available to a wide variety of invertebrates and seaweeds that would otherwise be outcompeted by mussels (Paine 1966, 1971; Duran and Castilla 1989). Likewise, herbivorous sea urchins and snails control the availability of critical resources (space and access to light) in tide pools by preferentially feeding on competitively dominant seaweeds (Dayton 1975; Lubchenco 1978). In terrestrial ecosystems, an increase in soil resources makes light relatively more limiting, shifting the competitive balance in favour of taller plants (Tilman 1985) and may increase the number of trophic levels that can be supported (Oksanen 1990; Power 1992). Thus, the impacts of resource supply on community structure extend well beyond the primary producers.

(2) The addition or loss of species that differ in their rates of resource consumption or the level to which resources are depleted can have either large or small effects on ecosystem processes, depending on their degree of overlap in resource use with other species in the community. Most plant species are similar to one another in the types of resources used (light, water and nutrients), although there can be specialization by rooting depth (see above), form of nitrogen utilized (Read 1991; Schulze *et al.* 1995), or the level to which soil resources are depleted (Tilman 1988). By contrast, animal and microbial disease organisms commonly vary in their degree of resource specialization and, therefore, in their degree of overlap with other species in a community. In many cases, specific traits of both the consumer and of the plant or prey, as well as characteristics of the environment in which the interaction occurs, determine the specific impact on rate of consumption of the resources or prey (Lubchenco and Gaines 1981).

Traits of plant species that best predict resource consumption are height (or biomass per individual) and relative growth rate (RGR) – traits that vary continuously among organisms (Grime and Hunt 1975) and that are unlikely to be strikingly distinct in any particular species (Figure 5.2-2a). Height (size) enhances resource capture in plants that are rooted to their substrates (e.g. terrestrial plants, aquatic macrophytes and sessile algae) by allowing the plant to reach the top of the canopy where most light is available and to exploit a large soil volume, whereas RGR is correlated with potential for carbon and nutrient acquisition (Olson and Lubchenco 1990; Lambers and Poorter 1992; Chapin 1993). In closed communities, any reduction in the abundance of one species should cause a compensatory increase in the abundance of other species due to release from competition, with little change in the total quantity of resources accumulated by vegetation at the ecosystem level (McNaughton 1977; Chapin and

Figure 5.2-3: Total biomass (excluding roots) of plant functional groups in arctic tussock tundra after 9 years of different environmental manipulations: control (C), nutrient addition (N), greenhouse which raised summer air temperature by 3°C (T), fertilized greenhouse (NT), and shading to reduce light by 50% (L) (Chapin *et al.* 1996).

Shaver 1985). Consequently, we expect that the gain or loss of a species will have little effect on biogeochemical cycles within the ecosystem under ‘steady-state’ conditions (Shaver *et al.* 1995), if these species differ only in resource consumption. This hypothesis is supported by ecological responses to experimental and natural variation in resource supply, both of which show much larger changes in the abundance of individual species than in biogeochemical pools or fluxes measured at the ecosystem level (Figure 5.2-3, Table 5.2-1; McNaughton 1977; Chapin and Shaver 1985; Aerts and Berendse 1988; Chapin *et al.* 1995). In summary, even large changes in species diversity and abundance may have only modest *direct, short-term* effects on pools and fluxes of carbon and nutrients, when species differ only in rates of resource consumption. Similarly, many animal species, particularly grazers, have a broad overlap in diet, such that a change in abundance of one species is compensated by changes in abundance of competing species with minimal effect on the rate of consumption of their common prey species (Frost *et al.* 1995).

Many animal species (and some plant species) differ strikingly from all other species in the community in the resources they consume and, therefore, their effects on community structure. Addition or deletion of these species strongly influences the abundance of the limiting resources or prey that they consume, because they use discretely different resources from other species in the community. These top-down controls are particularly well developed in aquatic systems, where removal of sea otters releases sea

Table 5.2-1: Annual variation in production (% of five-year mean) of major tussock-tundra species and total community above-ground production (Chapin and Shaver 1985).

Species	Production (% of average)					Coefficient of variation (%)
	1968	1969	1970	1978	1981	
<i>Eriophorum</i>	77	58	148	101	116	35
<i>Betula</i>	30	52	55	248	121	88
<i>Ledum</i>	106	138	62	103	91	27
<i>Vaccinium</i>	135	172	96	28	71	56
Total production	93	110	106	84	107	11

urchins which graze down kelp (Estes and Palmisano 1974), or the addition or removal of a fish species can have large ‘keystone’ effects that propagate down the food chain (Carpenter *et al.* 1992; Power 1992). Many non-aquatic ecosystems also exhibit strong responses to changes in predator abundance (Hairston *et al.* 1960; Strong 1992). For example, removal of wolves can release deer populations which graze down vegetation (Rasmussen 1941), while the removal of elephants or other keystone mammalian herbivores leads to encroachment of woody plants into savannas (Owen-Smith 1988; Wilson and Agnew 1992). Similarly, epidemic diseases, such as rinderpest in Africa, can act as keystone species by greatly modifying competitive interactions and community structure (Bond 1993).

The strong effects of grazers and predators on community structure automatically translate into effects on ecosystem structure, for example by greatly altering the biomass of primary producers (Power 1992), perhaps even on a biogeographic scale (Gaines and Lubchenco 1982; Zimov *et al.* in press). However, we have only fragmentary information on the ways in which this altered ecosystem structure modifies ecosystem processes. Often these top-down controls by herbivores and predators have a much greater effect on the biomass and species composition of lower trophic levels than on the flow of energy or nutrients through the ecosystem (Carpenter *et al.* 1985) because declines in producer biomass are compensated by increased productivity and nutrient cycling rates by the remaining organisms. For example, intensively grazed grassland systems such as the southern and southeastern Serengeti Plains (McNaughton 1985) have a low plant biomass but rapid cycling of carbon and nutrients due to treading and excretion by large mammals, which prevent the accumulation of standing dead litter and return nutrients to the soil in plant-available forms (McNaughton 1988). Keystone predators or grazers can thus alter the pathway of energy and nutrient flow and modify the balance between herbivore-based and detritus-based food chains.

We expect these generalizations about the importance of traits determining resource consumption to apply to closed

communities where resource supply rather than colonization determines productivity and nutrient cycling and where multiple species use the same limiting resources. However, disturbance regime strongly influences the expression of these ecosystem effects (Menge *et al.* 1994; see also 5.3.1). As disturbance rate and intensity increase, patterns of resource supply and consumption become less important determinants of ecosystem processes, and the impact of strong biotic interactions and keystone predators is diminished (Menge *et al.* 1994).

(3) Animals or plants that greatly alter disturbance regime can have large effects on ecosystems by decreasing the relative importance of equilibrium processes relative to non-equilibrium processes. This is one of the most important ways in which animals affect ecosystem processes (Lawton and Jones 1995). For example, gophers and pigs create large areas of soil disturbance, creating sites for seedling establishment and favouring early-successional species (Hobbs and Mooney 1991; Kotanen in press), generally leading to a lower biomass and a higher ratio of production to biomass (Shaver 1995). Bivalves that bore into coral reefs increase the rate of bioerosion of coral heads and thus their susceptibility to dislodgment during storms (Highsmith 1980). At the regional scale, disturbances created by overgrazing can alter the albedo of the land surface and change patterns of regional temperature and precipitation (Charney *et al.* 1977; Schlesinger *et al.* 1990).

Plants can also alter disturbance regime through their effects on soil stability and their flammability. For example, introduction of grasses into forest or shrubland ecosystems can increase fire frequency and cause a replacement of forest by savannah (D’Antonio and Vitousek 1992). Similarly, boreal conifers are more flammable than deciduous trees because of their large leaf and twig surface area, low moisture content and high resin content (van Cleve *et al.* 1991). Plants and animals can also act to decrease disturbance. In early succession, plants are often critical in stabilizing soils and reducing wind and soil

erosion. This allows successional development and retains the soil resources that determine the structure and productivity of late-successional stages. Similarly, variation in size and shape of seaweeds has a substantial impact on their susceptibility to disturbance from wave forces (Gaylord *et al.* 1994) and, therefore, on community patterns of disturbance and succession (Dayton 1975). Both plant and animal traits that alter disturbance regime tend to be discontinuous, which increases their probability of having a large ecological impact on any given ecosystem. The ecological impact of adding or deleting species which influence disturbance regime depends on whether there are other species in the ecosystem sharing these traits.

Disturbance regime has just as large an impact on structure and processes at the community as at the ecosystem level through its effects on competitive interactions among species with different life-history traits. Disturbance regime determines the competitive balance between early and late-successional species (Olff *et al.* 1993), often resulting in the greatest species diversity at intermediate levels of disturbance (Connell 1978; Sousa 1979; Paine and Levin 1981; see 5.3.1).

5.2.2.7 Ecosystem-level feedbacks to biodiversity of invasions and extinctions

In natural ecosystems, biodiversity may be of greater inherent interest to society than ecosystem processes, because many of the goods and services (direct benefits of species; Ehrlich and Ehrlich 1981) that people derive from ecosystems relate to properties of species rather than to biogeochemical processes. However, the existence and quality of the Earth's atmosphere, climate, water and soil ('indirect benefits' of species; Ehrlich and Ehrlich 1981; Chapter 5.1) depend on biogeochemical processes. We have established that species traits and biodiversity do have implications for ecosystem processes. We also know that species are quite sensitive to their environment and that subtle changes in environment can alter competitive balances or rates of predation or herbivory, leading to changes in species composition and biodiversity (Lubchenco 1978). Perhaps the most important consequences of changes in species traits and biodiversity in natural ecosystems have to do with the largely unknown feedbacks of the altered environment to further changes in biodiversity. For example, invasion by alien grasses in Hawaiian forests resulted in increased fire frequency and a decline in the diversity of fire-sensitive woody species (D'Antonio and Vitousek 1992).

A second, largely unexplored consequence of changing biodiversity involves species-specific interactions with other species that have large ecosystem effects (the fifth critical component of diversity). For example, a seed disperser or pollinator that has little direct effect on ecosystem processes may be essential for the persistence of

a canopy species with greater direct ecosystem impact (Gilbert 1980; Paine 1980). At our present level of ignorance, these *indirect* effects of species on ecosystem processes are difficult to predict, suggesting that we should be conservative in drawing conclusions about the ecosystem impacts of loss of a given species or level of diversity.

5.2.2.8 Conclusions

Five critical components of diversity required to predict the functional consequences of species additions or losses are (1) the number of species in a community, (2) the relative abundance of these species, (3) how strongly an invading or deleted species differs from other species in the community, (4) the traits of the species and (5) the indirect effects that a species has on other species in the community. The major mechanisms by which species alter ecosystem processes are through changes in soil resource supply, the consumption of resources or food, and disturbance regime.

The gain or loss of a species will have its greatest impact on ecosystem processes when there are few species in the community, when the species gained or lost is a dominant species, and/or when the species differs strongly from other species in the community. When species are similar to one another in their resource requirements, as often occurs with plants and generalist herbivores, the gain or loss of a species has a large effect on community composition but less effect on ecosystem processes because of the compensatory responses of other species to the altered competitive environment. Compensatory responses are most likely to occur where there are many species per functional group. The traits that govern resource acquisition in these species are often continuously distributed among species, so that species differ quantitatively rather than qualitatively in their effects on ecosystem processes.

By contrast, the gain or loss of species that consume unique food or soil resources or that alter resource supply or disturbance regime can have large effects on ecosystem processes, which propagate through the ecosystem through a chain of indirect effects. Traits governing these processes often differ qualitatively among species, so that changes in the abundance of these species have widespread community and ecosystem impacts. Species effects on ecosystem processes are often as large as direct climatic effects and must be included in predictive models of the role of terrestrial ecosystems in global processes.

Species diversity (independent of species traits) is functionally important because it provides insurance against large changes in ecosystem processes and may enhance the efficiency with which resources are captured from the environment and transferred among species. Because each species shows a unique response to climate and resources, any change in climate or climatic extremes

that is severe enough to cause extinction is less likely to eliminate all members of a functional group. The fewer species there are in a functional group or group of interacting species (e.g. pollinators), the more likely it is that any extinction event or series of such events will seriously affect the function associated with that functional group. Although species clearly differ in the magnitude of their impact on community and ecosystem processes, the differences among species in their responses to disturbances and environmental extremes and their indirect ecosystem effects, mediated by species interactions, make it unlikely that there is much, if any, ecological redundancy in communities over time scales of decades to centuries, the time period over which environmental policy should operate.

5.2.3 Effects of spatial structure on ecosystem functioning

5.2.3.1 Introduction

Species are the building blocks of ecosystems, and as described in Section 5.2.2, the loss of species can lead to changes in ecosystem attributes beyond the species level, e.g. biomass, productivity, disturbance frequency, and the rates of biogeochemical flows. Not all species are equal in terms of their influence on their ecosystem, but Section 5.2.2 indicated some types of species likely to have large impacts: animal species high in the food chain; plant species with a dominant influence on the resource supply, or on the composition of the soil or litter; and species with unique attributes, such as nitrogen-fixing plants in N-poor environments. In Section 5.2.2 it is also suggested that ecosystem attributes depend on the total diversity of the biota, above and beyond the contributions of particular species.

Here the effects of spatial structure on ecosystem functioning are addressed. By spatial structure we mean the sizes and shapes of patches of different types of habitat (here used synonymously with ecosystem), and the distances of these patches from one another. A solid base of theory and empirical evidence shows that spatial structure can profoundly influence the diversity, abundance and interactions of species in ecosystems. In other words, two otherwise similar natural areas, differing only in their spatial configuration, will differ in their species composition and thus in other ecosystem attributes. This is of key importance, since one of humans' most ubiquitous effects on ecosystems is to fragment them. Virtually all natural areas today are not only smaller in total extent, but also considerably patchier than they once were (Groom and Schumaker 1993). Here we explain why patchiness matters, and why spatial structure must be a central consideration in conservation plans.

At the present state of ecological knowledge there is little evidence linking spatial structure directly to flows of

matter and energy, or to other attributes of ecosystems beyond the level of species. This remains an extremely important area for research. However, all ecosystem properties depend ultimately on the biota. Therefore, we review the considerable evidence on the effect of spatial structure on species and their interactions, returning at the end to the possible consequences at other levels of ecosystem organization. (Also see Saunders *et al.* 1991 and Fahrig and Merriam 1994 for excellent reviews of the consequences of fragmentation.)

5.2.3.2 Effects of spatial structure on species diversity and abundance

Local extinction and metapopulations. Ecologists increasingly view most species as consisting of so-called 'metapopulations', i.e. networks of local populations occupying discontinuous habitats, but partly connected to one another by occasional dispersal (see also Section 4.4). Extinctions of these local populations ('local' as opposed to regional or global extinction) may occur frequently in some species, owing to disturbances, changes in the habitat, or natural catastrophes. This implies that the survival of some species may be dependent on the ongoing founding of new local populations. Theory suggests that the chances of persistence for a metapopulation depend on how many local populations and suitable habitat patches there are, the length of time each local population persists before becoming extinct, and the propensity of the species to disperse between habitat patches and found new populations on empty patches (Hanski 1989, 1991; Hanski and Gilpin 1991; Fahrig and Merriam 1994; Hastings and Harrison 1994).

The majority of empirical studies of metapopulations have been on insects and other small and short-lived animals. Similar patterns are likely to be found in other species, but at larger scales of space and time. One common pattern is a 'mainland–island' spatial structure, in which the metapopulation contains one or more local populations large enough to be in no immediate danger of extinction, as well as many smaller populations. The small populations blink in and out of existence, going extinct during droughts, floods, harsh winters or other adverse circumstances, and being recolonized by immigrants from the mainland. If dispersal is blocked, the small populations will cease to exist: if the mainland population is lost, the species will become regionally extinct. Well-documented examples include several species of spiders on small islands (Schoener and Spiller 1987; Schoener 1991), and butterflies on patches of habitat supporting the plants on which their caterpillars feed (Harrison *et al.* 1988; Thomas and Harrison 1992).

In an alternative pattern there is no mainland and all local populations are fairly susceptible to local extinction. In this case the regional survival of the species is much

more precarious: there must be enough populations and available habitat patches within the region, and rates of dispersal among them must be high enough, to allow the founding of local populations can keep pace with their extinction. An excellent example is provided by the pool frog *Rana lessonae* in Sweden, on the northern edge of its distribution. Frog populations in individual ponds naturally become extinct during severe winters, or when succession obliterates the ponds. However, because modern forestry practices are both reducing the number of ponds and obstructing the dispersal of frogs among ponds, the frog may be on its way to regional extinction (Sjogren 1991, 1994). Similar patterns have been observed in other amphibians in temporary ponds (Gill 1978; Sinsch 1992).

Consequences for diversity and abundance. When the metapopulation processes of local extinction and recolonization are important, they lead to an obvious pattern in a species' spatial distribution. Habitat patches that are large and/or close to other patches will support populations of the species most of the time, while small or isolated patches will more often be unoccupied. This pattern is seen in amphibians (Laan and Verboom 1990), birds (Opdam 1990; Verboom *et al.* 1991), mammals (Lawton and Woodroffe 1991; Peltonen and Hanski 1991), and butterflies (Thomas *et al.* 1992) in fragmented European landscapes. Most importantly, when this is the case the regional survival of the species may be highly sensitive to any further changes in the spatial structure of its habitat. It may quickly collapse to regional extinction if the size or number of habitat patches is reduced, the average distances among patches increases, or changes in the habitat between patches make dispersal more difficult.

Based on this evidence, we may expect human-induced fragmentation to reduce the diversity of native species in natural habitats. The types of species most likely to be lost are those with the highest rates of local extinction on small habitat patches, such as the top predators and other species with large body sizes and large area requirements. Also likeliest to be lost are those species with the lowest abilities to disperse among and colonize habitat patches, which include typical late-successional ('climax') species. Conversely, the species likeliest to survive fragmentation will be those best adapted to patchy and frequently disturbed environments, meaning the well-dispersing, early-successional ('weedy') species (Tilman *et al.* 1994). Moreover, even if outright extinctions do not happen immediately, fragmentation will tend to shift species' relative abundances within ecosystems, such that the population densities of weedy species will increase and those of climax species decrease.

We also know that the genetic diversity within species is profoundly affected, and usually reduced, by the

fragmentation, extinction and recolonization of populations (McCauley 1991). What we do not know, as yet, is how much the loss of genetic variation affects the prospects for species' survival (see also 4.2).

5.2.3.3 Effects of spatial structure on species interactions

Pollination. If spatial structure can affect the distributions and abundances of species, it follows that its consequences can cascade through communities of interacting species. Some of the best examples concern the coevolved relationships between plants and the animals that pollinate them, or disperse their seeds (Bawa 1990). In Sweden, the herb *Dianthus deltooides* receives fewer visits by pollinating butterflies, and therefore suffers lower seed set, because of population fragmentation (Jennersten 1988). In small remnant patches of *chaco* (dry forest) in Argentina, numerous plant species experience fewer visits by specialized native pollinators and more visits by generalist introduced honeybees (*Apis mellifera*), leading to reduced seed output (Aizen and Feinsinger 1994a, b). Many similar examples are reviewed by Saunders *et al.* (1991) and Rathcke and Jules (1993). Possible consequences for plant populations include declining abundance, loss of genetic diversity and eventual extinction.

Herbivory. Because of their large area requirements, large mammals are usually among the first animal species to disappear from fragmented forests. Their loss may affect the structure of the entire forest because of the role they play as seed predators and herbivores. Leigh *et al.* (1993) examined small islands of tropical forest formed by the construction of a dam in Panama, and found they had fewer tree species than the forests on the nearby mainland. The islands were dominated by a few tree species whose seeds, on the mainland, were favoured foods of mammals such as agoutis. The absence of agoutis on the islands allowed these trees to become the dominant competitors, reducing overall diversity. Similarly, Dirzo and Miranda (1991) found that the absence of mammalian herbivores from small forest fragments in Mexico led to higher competition among tree seedlings, which led to forests dominated by a few competitively superior tree species.

Predation. Very important ecosystem services are provided by predators that control populations of herbivores, especially herbivores with potentially large effects on biomass and nutrient cycling. Large predators are especially likely to become scarce or disappear from fragmented ecosystems, for the reasons discussed above. Losing lions or cheetahs from fragmented African savannas may have enormous impacts on the vegetation and fire regimes, for example – effects that will be played out over the next several decades or centuries.

This point is best illustrated by predatory insects that can also have large ecosystem effects, but on faster time scales. Many herbivorous insects can undergo outbreaks that

devastate forests or other natural habitats. Ecologists believe that a major natural role in suppressing outbreaks is played by so-called parasitoids, which are insects (usually wasps or flies) that lay their eggs on the bodies of living host insects (which may be herbivorous 'pest' species). The developing larva of the parasitoid subsequently kills the host insect. Roland (1993) found that outbreaks of tent caterpillars lasted longer in heavily fragmented Canadian forests than in less fragmented ones, possibly because parasitoids were less efficient at finding their hosts (caterpillars) in patchy forests. Kruess and Tscharntke (1994) found that in agro-ecosystems as well, fragmentation can lead to fewer parasitoids and more herbivorous insects on plants.

Conversely, fragmentation can also allow natural habitats to be invaded by predators that are scarce in less disturbed situations. Many studies have reported that birds breeding in remnant patches of forest suffer elevated losses of eggs and nestlings to domestic cats, avian brood parasites (e.g. cuckoos), and other predators that thrive in the surrounding human-dominated landscape (Wilcove 1985; Andren and Angelstam 1988; Small and Hunter 1988; Paton 1994). Fragmentation may also influence the prevalence and spread of pathogens (Jarosz and Burdon 1991; Grosholz 1993).

Decomposition. One of the most direct links between fragmentation and ecosystem processes was found by Klein (1989), who examined communities of dung beetles in remnant patches of Amazon Basin forest. Dung beetles are extremely important recyclers of organic matter in nutrient-poor tropical forests. Klein found that forest fragmentation not only altered species composition, with fewer species of dung beetles (and sparser populations) in small patches than in larger tracts of forest, but also led to lower rates of dung decomposition, indicating a significant change in nutrient processing. Although this is an isolated example, it may not be at all unusual. We simply do not know how many changes of ecosystem significance are happening in tropical forests, which are extraordinarily rich in species and specialized interactions, very poorly understood by biologists, and currently threatened by rapid and severe fragmentation.

5.2.3.4 Spatial structure and ecosystems

We have seen that spatial structure has major effects on species composition, abundance, and interactions between species in ecosystems. At present we cannot make definite statements about the consequences of spatial structure at other levels of ecosystem organization, such as disturbance rates or biogeochemical flows. However, we have seen that the kinds of species most sensitive to spatial structure include top predators and other large, area-sensitive species; late-successional ('climax') species, which tend to be poorer dispersers than early-successional ('weedy')

species; and species involved in obligate pollination or seed dispersal mutualisms, which disproportionately tend to be tropical and late-successional. Comparing this with the list of species most likely to have large influences on their ecosystems (5.2.2), we see considerable overlap, suggesting the scope for far-reaching consequences of altering the spatial structure of ecosystems.

The growing recognition by ecologists of the importance of spatial structure is being put into practice in attempts to conserve individual species. As conservationists attempt to design plans for large-bodied, fragmentation-sensitive species such as the northern spotted owl, the core principles are to make individual patches large enough for the rate of local extinction not to be too high, as well as close enough together (or connected by 'corridors' of habitat) for rates of dispersal and recolonization to be adequate (Doak 1989; Lamberson *et al.* 1992; but see Harrison *et al.* 1993).

However, one general problem with these strategies is that the responses of individual species to fragmentation are highly dependent on details of the species' demography and dispersal behaviour (Fahrig and Merriam 1994; Harrison 1994). We know too few of these idiosyncratic details, for any species, to predict with any confidence whether it can survive in a given fragmented landscape. Worse yet, a landscape that supports a viable metapopulation of one species may easily fail to do so for many others. Few principles exist yet to guide us in the conservation of entire fragmented ecosystems, except that, almost certainly, the less additional fragmentation we impose on them the better they will function at all levels of organization.

5.2.4 Biodiversity at landscape to regional scales

5.2.4.1 Introduction

Most of the current emphasis on biodiversity has been focused on taxonomic or functional diversity. Even at the scale of ecosystems, the largest proportion of effort has

been focused on the relationship between species diversity and ecosystem functioning. While such work is of critical importance, it does not capture larger-scale patterns and processes, specifically those at the landscape to regional scale. At these large spatial scales, the appropriate biological unit that confers diversity is the ecosystem. Landscapes are composed of an assemblage of interacting ecosystems. A diverse landscape or region is one with many different ecosystems (richness component), or one in which the area occupied is similar for all ecosystems (evenness component). The key characteristic of a diverse landscape or region is that its constituent ecosystems perform different functions – physical, biological or human-related. Here, we do not address species or population diversity that occurs at large scales, nor heterogeneity induced at the scale of individuals (i.e. ‘gap dynamics’), nor patchiness within an ecosystem. Rather, we focus our discussion at scales that are relevant to processes that occur at the landscape to regional scale: watershed dynamics, gaseous and energy exchange with the atmosphere, and socioeconomic and political dynamics.

These processes are responsible for the interactions between ecological units and global change, and we will refer to them as ‘landscape or regional functions’.

Humans have demonstrated world-wide that alteration of the constituent ecosystems within landscapes and regions through land-use management can fundamentally alter local and global-scale hydrological cycles, atmospheric chemistry, terrestrial carbon storage, soil erosion rates, water quality and human welfare. A careful analysis of the role of biodiversity at large scales is therefore important for understanding and managing long-term global sustainability.

Our objective here is to explore the conditions under which biodiversity at landscape to regional scales is important for the large-scale system functions identified above. We will first set forth some ideas about a general relationship between biodiversity and landscape to regional function, providing examples from a diverse literature. Second, we will assess the types of landscapes or regions in which rare ecosystem types contribute largely to ecosystem functioning. Finally, we will assess the relationship of human land-use diversity to the functioning of both ecological and human systems.

5.2.4.2 Diversity and ecosystem functioning at landscape to regional scales

Conceptual framework: The extent to which biodiversity matters in a landscape or region is at least partly dependent upon the linkages among ecosystems. The currency of these linkages includes wind, water, trace gas exchange, plant and animal movements and human products and revenues. Certain ecosystems within a landscape or region may serve as sources of materials, energy or biota (Pulliam 1988), while others may serve as sinks. Risser (1987) and

Forman and Godron (1986) suggested that disturbances increase the rate of material flow among landscape units, but that fragmentation may also reduce flows and linkages.

The relationship between diversity and system functioning at large scales has strong analogies to generalizations made for the scale of species and functional-type diversity and ecosystem functioning by Sala *et al.* (1996). First, to understand the relationship between ecosystem diversity and landscape or regional function, one must understand the contribution of the various ecosystems to the specific function of interest, i.e. element export, gaseous flux, revenue, etc. Once this is understood, the relationship between diversity and function becomes clearer: deletion, disturbance or increases in the abundance of the ecosystem that contributes the most to the specific function will have the largest effect. In many cases the most abundant ecosystem will be the one that contributes the largest proportion to landscape or regional function. In some specific cases, there may be ‘keystone’ ecosystem types that are relatively rare within the landscape or region, but that provide a disproportionate contribution to function at that scale.

In many landscapes or regions, the presence of several ecosystem types that have high proportional land cover is most important in determining large-scale system functioning, for instance in susceptibility to disturbance. Human activity in such landscapes often preferentially reduces the abundance of one or more of these dominant ecosystem types, and thus may impact system functioning significantly. High-productivity ecosystems, such as the fertile tropical rain forests of the Amazon and the tallgrass prairie of North America are among the most likely to be cultivated or harvested. The impacts of reducing such dominant ecosystem types may be highly significant for landscape and regional function, resulting in large-scale habitat changes, alteration of storage or runoff of water, and associated consequences for sediment production, or altered carbon and nitrogen balance. In addition, in landscapes or regions that contain ‘keystone’ ecosystems, human interference with ecosystem functioning may have very dramatic influences, such as complete elimination of a crucial ecosystem function such as water storage.

Examples: Ecosystem diversity at landscape and regional scales is controlled by the interactions among large-scale patterns in climate and large and small scale heterogeneity in the physical environment. A diverse array of ecosystems within landscapes or regions may be important for providing both sources and sinks of propagules, fauna, sediments, water or nutrients. If the array contains an adequate balance of ecosystems that serve each of these functions, the function at the landscape or regional scale is likely to be able to persist in the face of disturbances. We will provide four examples, with particular attention to the

Figure 5.2-4: Potential natural vegetation of the central grasslands of the USA. Revised from Küchler 1964.

central grassland region of the USA, the system for which we have the most information and experience.

In central North America there is a strong west–east gradient in mean annual precipitation from the eastern foothills of the Rocky Mountains to the Mississippi River. Additionally, there is a nearly orthogonal north–south gradient in mean annual temperature. These gradients interact to provide regional-scale patterns in ecosystem types (Figure 5.2-4). These regional-scale patterns interact with small-scale patterns of topography and parent materials to produce an increasingly complex pattern of ecosystems as one scales down from the region to individual landscapes. At a mesoscale level (hundreds of km²), the Sand Hills of Nebraska provide a classic example of the effect of parent material on ecosystem development. Because of their effect of reducing evaporative losses and therefore increasing the effectiveness of precipitation (Noy-Meir 1973), these deep sandy soils (Figure 5.2-5) result in a westward extension of the tallgrass prairie into an area in which the typical vegetation is classified as northern mixed prairie (see Figure 5.2-4). Here, landscape-scale topographic gradients can result in gradients in ecosystem types over tens of metres.

This complex of scales of heterogeneity in both environments and ecosystems provides the grassland region with enormous response potential to certain large-scale disturbances such as climate change. This complex geographic mixing of ecosystem types changes the nature of the responses that will be necessary for the region to

adapt to new climatic changes. Instead of requiring regional-scale migration of species adapted to the new climate, response to climate change will in many cases only require local-scale dispersal. In addition, it is important to note that this regional distribution of soils and of ecosystem types has developed over many thousands of years: consideration of long time scales may be important for any assessment of the origin and maintenance of large-scale diversity.

A second example of the importance of landscape-scale heterogeneity occurs in systems that are subjected to large-scale fires. In coniferous subalpine forests, topographic variability results in a complex of ecosystem types, including forest successional stages, meadows and xeric vegetation (Romme and Knight 1981). This landscape-scale heterogeneity in ecosystem types, caused by physical patterns in drainage and nutrient availability, as well as by successional dynamics, results in natural fire-breaks which may reduce the likelihood of very large fires (Romme and Knight 1981; Romme 1982). Recent work in Yellowstone National Park in the USA has suggested that heterogeneous landscapes are more resistant to large fires than homogeneous landscapes, and that once burned, they have a greater ability to maintain water quality (Knight and Wallace 1989).

A third example is found in the interaction of migratory and other large fauna and the structure and function of landscapes and regions. A very large proportion of the world's fauna in subtropical to arctic regions depends upon multiple habitats which are used seasonally. Wild ungulate movements have been shown to influence significantly the patterns of net primary production, forage utilization and nutrient cycling (Ruess and Seagle 1994) at both landscape and regional scales. Coughenour (1991) suggested that for antelope (*Saiga tatarica*) in southern Asia, wildebeest in the Serengeti, and bison in North America, migration helps to conserve forage and protect landscapes from overgrazing. Interference in the ability of these ungulates to utilize a diversity of habitats through spatial constraints or habitat elimination has had very large impacts on ecosystem functioning, through local overabundance of herbivores or by removal of natural grazing (reviewed by Coughenour 1991). Maintenance of corridors for faunal migration may significantly enhance the ability of organisms to distribute their habitat use across broad regions (Forman 1987).

Landscape diversity and function may rely upon population dynamics of a single species. For example, beaver (*Castor canadensis*) in the boreal forest of North America have been shown to alter the distribution of hydrologic zones (forest, wet and dry meadows and ponds) (Naiman *et al.* 1994). The net effect of increasing beaver populations has been to convert forests into meadows and ponds, increasing the abundance and cover

of these ecosystems from minor constituents to the majority of land cover (Bridgham *et al.* 1995). The anaerobic conditions created by these ecosystems have altered regional biogeochemical processes, potentially doubling or tripling methane flux from the boreal forest (Bridgham *et al.* 1995), a significant constituent of the global flux. In addition, beaver activity influences the movement and accumulation of nutrients and water through alteration of drainage networks, an effect that may last for decades or even centuries (Naiman *et al.* 1994). In this example, a previously minor ecosystem type has increased in abundance and brought about change in a large-scale function.

Finally, landscapes in many areas of the world are subjected to anthropogenic inputs of sulphate and nitrate, causing net acidification. Within such landscapes, some of the ecosystems, such as coniferous forests, streams and oligotrophic lakes, have a very high sensitivity to such inputs. The presence of other ecosystems within these watersheds, capable of providing a sink for acidity or of providing a source of basic cations, has been demonstrated to be crucial for the continued functioning of these systems. This has been shown to be true particularly for streams and lakes in mountainous regions (Johnson *et al.* 1981; Charles 1991). Acidity that falls in mountainous regions is often not sufficiently filtered until it has passed through the soils of deciduous forests or subalpine bogs. Streams and lakes are dependent upon a relatively large areal extent of ‘sink’ systems in order to resist large-scale biological impacts resulting from net acidification.

5.2.4.3 Keystone ecosystems

There are several examples of ecosystems that contribute specialized functions to landscapes or regions despite being very small. The presence of such an ecosystem may add only a small increment to an index of ‘diversity’ based upon richness or evenness of ecosystem types, but may have a very significant influence on large-scale system functioning. Human interference with such ‘keystone’ ecosystems may occur at very small spatial scales, but may have dramatic effects at landscape to regional scale.

Riparian ecosystems, because of their physical and biological components, have a specialized function in landscapes and regions. They are well recognized for their abilities to filter sediments in overland flow, and to retain nutrients in overland flow and subsurface water movement (Gregory *et al.* 1991). For example, in an experimental watershed in Maryland, USA, croplands released considerable proportions of nitrogen and phosphorus received in a given year (92% and 59% of inputs, respectively), while riparian forests maintained most nutrient inputs (releasing 11% of nitrogen and 20% of phosphorus inputs) (Peterjohn and Correll 1984), including

Figure 5.2-5: Sand content in the central grasslands of the USA. Data from USDA Soil Conservation Service 1989.

those received from adjacent croplands. When riparian biota are disturbed or destroyed, severe sedimentation and nutrient loading may occur. Riparian systems may be one of the best examples of ‘keystone’ elements in landscape diversity, because their influence is out of all proportion to their size.

Wetlands have long been recognized as providing a key role in absorption of phosphate and other materials that are harmful to aquatic systems (Verry and Timmons 1982; Urban *et al.* 1989). Anthropogenic sources of phosphate have major implications for the functioning of natural aquatic systems (e.g. Schindler 1974, and many others), causing algal blooms, increased consumer activities, oxygen deficits and large-scale fish kills. Although wetlands may provide a critical function in phosphate absorption, Richardson (1985) demonstrated that wetlands may saturate with phosphate under very high input more rapidly than ecosystems that have high levels of amorphous iron oxides in soils. These results suggest that a diverse array of surrounding terrestrial ecosystems may make critical contributions to the functioning of landscapes undergoing extreme stress.

Many other keystone ecosystems have been documented in the literature, for instance prairie potholes (Poiani and Johnson 1993) and tropical lagoons or mangroves (Morell and Corredor 1993). Clearly, identification of keystone ecosystems and their relationship to landscape or regional functioning should be a high priority.

Figure 5.2-6: Land use in the central grasslands of the USA. Data from USDI US Geological Survey 1986.

5.2.4.4 Land-use diversity

One of the distinctive properties of landscapes or regions, as opposed to smaller units, is the extent to which humans must be considered a part of the system. Ecosystems are managed at spatial scales from landscapes to regions. Humans change the character of the ecosystems they manage by altering their properties with respect to exchange of nutrients, energy and sediments, and with respect to additional substances such as toxins or fertilizers. Inclusion of human processes as part of landscape and regional functioning is therefore necessary for any understanding of causes and effects at these scales (Naveh 1971). Furthermore, the structure of landscapes and regions has a large impact on patterns of human occupation, on land-use decisions, and on cultural and economic conditions. An integrated approach to human and ecological systems is the most appropriate approach to understanding landscape and regional functioning.

Probably the clearest examples of landscapes and regions that include a large diversity of ecosystem types are found in areas in which some of the natural ecosystems have been replaced with intensively managed ecosystems producing commodities such as timber or grain. This heterogeneity has tremendous consequences for landscape or regional-scale processes, including nutrient and sediment redistribution, and gaseous exchange with the atmosphere. Here, we will identify the causes of large-scale heterogeneity in land-use management practices, and discuss the significance of the

resulting heterogeneity for the functioning of landscapes and regions.

Heterogeneity in land-use is the result of interactions between climatic and edaphic constraints and human socioeconomic forces. Macroclimatic zones generally determine the range of land use management practices that are biologically and economically feasible in a region and therefore have a large influence on ecosystem diversity. For example, in the central grasslands of the USA (Figure 5.2-6), the distribution of cropland versus rangeland is generally controlled by precipitation, but patterns are modified locally by soil texture and depth, and by the availability of surface or ground water for use in irrigation. Qualitative evaluation of Figure 5.2-6 suggests an ecosystem analogue to the relationship that Whittaker and Niering (1975) reported for species diversity along a moisture gradient.

It appears that land-use diversity is low in the driest and wettest parts of the central grassland region. In the driest areas, along the eastern margin of the Rocky Mountains, landscapes are dominated by native grasslands because water availability limits crop production. In the wettest parts of the region, landscapes are dominated by cropland ecosystems because water availability is so favourable for crop production. The intermediate areas are mixtures of grassland and cropland ecosystems and have the highest landscape diversity. Social, cultural and economic conditions interact with environmental constraints to produce these observed patterns of land use (Riebsame *et al.* 1994).

In highly managed regions, human systems may be best maintained where land-use management practices have resulted in a pattern of ecosystem types that confers functional diversity for both ecological and economic systems. Cultivated ecosystems generally function as sources of sediments, as sources of trace gases such as ammonia, as areas that have net reductions in carbon storage, and as sources of cash revenue. To maintain regional functioning, we suggest that these systems must be balanced by ecosystems that can capture sediments, produce less (or even consume) trace gases, and serve as net carbon sinks. Naveh (1971) argued that human activity in Mediterranean ecosystems may be directed to the maintenance of a sufficient level of ecological diversity. We provide below two examples of systems that may be considered sufficiently diverse for ecosystem and human system functioning, and an example of one that may not.

The central grasslands of North America comprise a mosaic of land use, ranging from intensively cropped dryland systems to irrigated cropland and native grassland used for beef production. An index of land-use diversity for the region would probably be high, given the spatial complexity and the number of crop types distributed throughout the region. In terms of ecosystem functioning, the presence of native grasslands in this matrix, rather than

the diversity *per se*, may be extremely important. Cultivation results in significant regional losses of carbon through increasing decomposition and erosion which reduce the amount of organic matter in the soil (Burke *et al.* 1991). The presence of native grasslands is important for minimizing those carbon losses at a regional scale. The grasslands evolved in the presence of large generalist herbivores and appear to be well adapted to withstand domestic livestock grazing (Milchunas *et al.* 1988). In addition, cattle feedlot operations in the region produce large amounts of methane. While all soils in the region have net methane consumption, the grassland systems have significantly higher methane consumption than cultivated areas, and the presence of such sinks reduces the net regional methane contribution to the atmosphere (Mosier *et al.* 1991). In this case, diversity of land uses does not produce a 'better' balance of trace gas emissions (i.e. the lowest possible level of emissions), but, given that humans must use the area for grain production, the presence and distribution of the native grasslands is crucial for minimizing regional human impacts.

If we consider the dynamics of human populations, the presence and distribution of both grassland and cropland ecosystems may also be important for social and economic stability. Climatic variability in the region has produced large fluctuations in ecosystem production, economic welfare and land-use management (Albertson and Weaver 1944). For example, during the 1930s, a prolonged period of low precipitation resulted in failures of the winter wheat crop in the southwestern part of the region. Winter wheat requires sufficient soil water in the autumn to germinate and establish and enough water during the winter to promote tiller survival. Spring moisture is required for plant growth, flowering and grain production. By contrast, early and mid-summer soil water is necessary to promote forage production by the native grasslands. The probability of failures of both the winter wheat and forage crops in any given year is relatively low. Hence, the stability of human socioeconomic systems in the region is greater in the presence of both ranching and farming operations than it would be if only one land-use type were available.

Tropical deforestation in the Brazilian Amazon provides an example of the genesis of spatial patterns of ecosystems as a result of human use. In this case, a region dominated by a single ecosystem type (forest) is being made more diverse by adding a variety of crop and pasture ecosystem types. Skole and Tucker (1993) used satellite data to estimate that the area of the Amazon affected by deforestation increased from 78 000 km² in 1978 to 230 000 km² in 1988. This was accompanied by an increase in the total area of forest fragments (<100 km²) from 5115 km² to 16 228 km², suggesting that large blocks of forest are increasingly being broken up into smaller blocks. The 1990 IPCC estimate of net release of carbon to

the atmosphere as a result of tropical deforestation is 1.6 ± 1.0 Pg (Houghton *et al.* 1990). Initial studies of the effects of deforestation on other trace gases suggested that conversion to pasture was resulting in increases in N₂O-N of up to 1 Tg per year (Luizao *et al.* 1990). However, recent work has significantly altered our understanding by assessing the interactions of successional dynamics with trace gas fluxes. Keller *et al.* (1993) demonstrated that nitrogen oxide fluxes increase following conversion to pasture, but that these fluxes decrease to levels below those in forests after ten years. Similarly, they found that forest soils consume methane, and that recent, moist pastures are net producers of methane: however, these fluxes are reduced to predisturbance levels during secondary succession (Keller and Reiners 1994). Clearly, deforestation is altering regional and continental-scale processes: however, it is very important to note that the relationship of successional dynamics to these processes is complex and deserving of further study.

A final example of an intensively managed region is the Loess Plateau of China. Here, the spatial pattern of land-use management is apparently very diverse. There are large numbers of cultivated patches on valley bottoms, slopes (terraced or unterraced) and some remnant uplands, and grazing lands are located on the very steep dissected slopes. However, the ecological stability of the region is extremely low, due to the intensity with which each hectare of land is used. Many of the slopes are cultivated without building terraced fields, and the natural grasslands and shrublands on slopes have been so severely grazed that the vegetation is sparse and in many places the soils are bare. These land-use patterns combine with unfavourable natural conditions – namely loess consisting mainly of silt with porous structure and well-developed cleavages, and precipitation that is concentrated in the summer usually falling as high-intensity storms. Thus, the region is subjected to very high rates of erosion, and high rates of sediment loss. As a result, the Yellow River leaving the Loess Plateau carries an enormous sediment load (approximately 1.6×10^9 tonnes per year) (Integrated Scientific Research Team of the Loess Plateau of CAS, 1990), which makes it unsuitable for most natural biological activity and causes enormous deposition problems downstream. Human populations in the region are large, and expanding rapidly, which is placing increasingly heavy demands upon an already intensively utilized landscape. Inhabitants continue to cultivate more hillslopes and to graze the degraded grassland and shrubland ecosystems more intensively. Many of the flocks of sheep and goats are kept for personal status, not for food production, so over many areas the intensive grazing that is degrading the ecosystems adds relatively few commodities to the market-based economy of the region. In the Loess Plateau region, the fact that the landscape is diverse does

not alter the fact that almost the entire region serves as a net source of sediment.

5.2.4.5 Summary

Human use of ecosystems has sparked a world-wide concern for its effects on biodiversity. To a large extent the focus of concern has been on losses of species from ecosystems, and this in turn has raised the issue of the relationship between species diversity and ecosystem functioning. While this concern and effort is warranted and important, it does not deal fully with the issue of biodiversity. What is missing in this approach is the investigation of the diversity of ecosystems in landscapes and regions.

Diversity at the scale of landscapes and regions is related to hydrological balance, biotic interactions, trace gas fluxes and other large-scale processes, but the nature of the relationship appears to be landscape- or region-specific. Human activities have greatly altered broad-scale patterns of diversity, and a significant challenge remains regarding how to balance ecological functioning with human needs. Which ecosystems within landscapes play keystone roles? And how do we maintain natural processes, and hence diversity, while meeting the human demands of landscapes and regions?

5.3 Drivers and dynamics of changes in biodiversity

5.3.1 Overview of disturbance

The relationship between biodiversity and disturbance has several important aspects. First, there can be both direct and indirect relationships between the two phenomena, although the indirect relationships are not yet well understood. Secondly, both biodiversity and disturbance are hierarchical concepts (Table 5.3-1), with different expressions at different levels of organization, such as organisms, populations, communities and ecosystems (Pickett *et al.* 1989). This indicates that the relationship between them may change as one focuses on different

levels of organization. Thus, events that disturb a community may not disturb a landscape. Thirdly, in order to understand the relationship between biodiversity and disturbance, several important clarifications about disturbance must be borne in mind. (1) Discussion of disturbance cannot be productive without an explicit, if perhaps tentative, model of the components, interactions and scale of the system of interest (Kolasa and Pickett 1989). Otherwise it will be impossible even to say what is or is not a disturbance or to disentangle the effects of disturbance and stress. (2) Assessment of disturbance requires a reference state (Rykiel 1985). Such reference states can be arbitrarily set, culturally determined, or derived from historical or palaeo-ecological records as long as the important past or external determinants of the system are known (Pickett *et al.* 1992) (3) Non-arbitrary reference states can be supplied by models of the system that specify the components and interactions of the system that are needed for that system to persist. Even in transient systems that are accidents of a certain time and place, such a model can be valuable in discerning disturbance and stress. Without substantial progress toward the rigour outlined above, the relationships between biodiversity and disturbance may be difficult to discover, let alone generalize or apply to management. Generalization must not, for example, mix different hierarchical levels of organization at which the expressions and mechanisms of interaction between biodiversity and disturbance are necessarily different.

Given the caveats above, disturbance is most generally defined as a physical disruption of the structure of a system. The system must be represented by an explicit model that specifies the components and the interactions within it. Placing the model in a hierarchical context indicates how particular disturbance events may or may not spread or affect other levels of organization or scale. The discussion that follows focuses on the ecological rather than the evolutionary impact of disturbance.

5.3.1.1 Characteristics of disturbance

It is important to specify the several dimensions characterizing disturbance (White 1979). The first characteristic is the identity of the event(s). What are the types of disturbance that act in a system? A caution to be applied here is that labelling events simply as fire or flood, for example, may not be adequate. Certain kinds of fire, or certain kinds of flood, may have both qualitatively and quantitatively different impacts on ecological systems at different levels of organization. The need for a model of the system must be re-emphasized here. It is simply impossible to say what is a disturbance without an explicit model of the system that specifies scale and organizational level.

Disturbance has intensity or severity (White and Pickett 1985). Although some might wish to characterize intensity

Table 5.3-1: Disturbance and biodiversity as expressed at different ecological levels of organization. Note that the scale at which an agent of disturbance acts may change the level of organization it impacts. Therefore the same agent may or may not act as a disturbance on different levels of organization.

Level	Illustrative element of biodiversity	Example of disturbance agent
Individual	Genotype	Predation
Population	Age structure	Disease
Community	Successional status	Lightning strike
Landscape	Patch type	Grazing exclusion
Biome	Ecoregion	Climate shift

by the amount of energy expended by the disturbance event, such a strategy will leave much of what is ecologically important about the disturbance hidden. It is not simply the force expended in blowing down a forest, for example, that is important in determining the response to that disturbance. It is also the nature of the substrate that results (White and Pickett 1985). How much of the soil is exhumed with the upturned roots of trees as opposed to merely being covered with debris resulting from the snapping of trees? In the case of fire, how patchy is the surface that is burned, and how much legacy remains from before the fire? And in another scenario, how many trees are defoliated by a herbivore at outbreak densities? Certainly, comparing vastly different intensities of disturbances as measured by energy expended by the event may lead to important generalizations about the nature of the template the disturbance leaves and the subsequent reorganization of the system, but at this stage in the development of disturbance theory, measuring intensity as energy expenditure alone seems inadequate. Joint characterization of disturbance events by energy expenditure *and* the nature of the habitat template they produce may be more promising (Barry and Dayton 1991).

Disturbances return to sites with some characteristic frequency (White and Pickett 1985). To speak figuratively, lightning does strike repeatedly at a site, and the ecological question is – how often? Stratifying the frequency by intensity is valuable additional information. Frequency can be specified in absolute terms or in terms relative to the temporal extent of the process or longevity of the system of interest. Typically, old-growth mesic, broad-leaved forests in many parts of the world experience treefalls at a given point once in 100 to 120 years (Hartshorn 1978; Reiners 1983). Boreal forests, having fire as the dominant disturbance, experience shorter return times (e.g. Heinselman 1973). Montane coniferous forests in wet environments generally turn over more slowly (Dale *et al.* 1986), although there is considerable variation based on site and community characteristics (Zackrisson 1977). Insect populations reach outbreak levels and disturb forest

canopies at intervals dependent on landscape and climate (Nothnagle and Schultz 1987).

The spatial scale and distribution of the disturbance is important as well (White and Pickett 1985). How large are the individual events relative to the size of the system? How are the events distributed in space? Are they near one another, or isolated? Answers to these questions about scale will help explain and predict the impact of disturbances on systems. For example, a chequerboard pattern of clearcuts intended to retain intact forest patches in a landscape is actually less likely to maintain old growth forest interiors in the Pacific Northwest than is contiguous cutting of an equivalent area (Franklin and Forman 1989).

Combining type, frequency and scale characterizes a disturbance regime (White and Pickett 1985). The term ‘regime’ could be replaced by pattern, as there is no necessity for constancy of pattern. Yet, different environments, landforms, human and natural landscapes, and regions can be characterized by the kind, recurrence and spatial pattern of disturbances within them. The term alerts ecologists to be prepared for regularities in patterns of disturbance that can evolutionarily select (Huston *et al.* 1988) or ecologically assort species (Noble and Slatyer 1980), in the same way that general patterns in climate may do. Indeed, natural disturbance regimes owe much of their regularity or repeatability to climatic patterns. Such a link points out the potential sensitivity of disturbance regimes to global climate change. Models that rely on the relative repeatability of disturbance regimes can successfully account for species distributions and behaviours (Waring and Schlesinger 1985; Horn *et al.* 1989). This is an important intersection between biodiversity and disturbance.

5.3.1.2 Relationship of disturbance to other ecological processes

In one system of characterizing disturbance, two additional factors are considered. Given the conceptual refinements above, these factors are more appropriately applied to stress, or to the inclusive concept of perturbation which includes both disturbance and stress.

One feature – the point of impact or point of pressure on a system – is a partial substitute for not having a specific model of the system, as discussed above. In both approaches, the idea is that different aspects of the natural world will be differentially sensitive to disturbance. Indeed, some will be immune to certain common events. This differential sensitivity must be known to study the relationship between biodiversity and disturbance.

The second feature that is more appropriate to the concept of stress or the inclusive concept of perturbation is duration. Disturbances are by definition discrete events (White and Pickett 1985). They may of course emerge from cumulative effects of stress, as when a grassland community is opened catastrophically by the aggregate effects of drought stress (e.g. Weaver and Albertson 1943). But the event of opening the canopy and root mat of the grassland community is discrete relative to the long persistence of such communities. It is important to recognize that the temporal patterns of disturbance as indicated by frequency, and the unusual juxtapositions of usual disturbance events in time, may result in ecological effects that are qualitatively or quantitatively different from the customary disturbance regime.

One of the emergent insights about disturbance is that it can operate in a similar way to predation as a disrupter of competitive exclusion and equilibrium species composition that would result from unchecked competition (Denslow 1985). This insight is encapsulated in the term ‘non-equilibrium coexistence’ (Connell and Keough 1985; Huston 1979) (see Chapter 4.5). Of course, coexistence determined by predation and by disturbance (acting with other factors) can establish an equilibrium composition. The term ‘non-equilibrium’ emphasizes the need to include other factors that can maintain communities in an equilibrium different from that achieved exclusively as a result of competition (Pickett 1980). The continued study of disturbance has confirmed this early insight (Loucks 1970).

5.3.1.3 Principles of disturbance

Most generalizations about disturbance currently stand as hypotheses, and focus on intermediacy of intensity, but more commonly, of frequency (Connell 1978; Lubchenco and Menge 1978; Huston 1979). The insight that diversity is expected to be maximized at intermediate frequencies or intensities of disturbance is called the ‘intermediate disturbance hypothesis’. A majority of species could not survive very intense disturbances. Nor could most species persist in the highly competitive communities that arise when disturbance is infrequent or very mild (Horn 1974). Likewise, productivity can show the same pattern (Reiners 1983). These generalizations must be constrained by underlying fertility gradients (Tilman 1988; Grime and Hodgson 1992; Grace 1993), the life histories of the species

available, and the existence of competitive hierarchies (Connell and Keough 1985). In systems where competitive hierarchies exist, higher fertility is expected to increase the rate of exclusion of poorer competitors, and higher rates of disturbance are thus required to reduce competitive exclusion in such environments. Furthermore, life-history features of the species pool determine the mode and success of reinvasion or persistence in a site after disturbance.

Models of population extinction and recolonization in a patchy environment have shown the importance of effective recolonization rates of poorer competitors, spatial aggregation of superior competitors and alternative local equilibria, among other factors (Hanski 1995). Source–sink relationships in a metapopulation are key causes of species coexistence in patchy landscapes (Pulliam 1988; Opdam 1991).

The temporal and spatial patterns of disturbance, and the responses of communities and ecosystems to them at the landscape scale, can be summarized as patch dynamics. Disturbed patches can be treated as populations, with birth, growth, size and age distributions, and death of patches (Levin and Paine 1974; Whittaker and Levin 1977; Pickett and Thompson 1978; Levin 1986). On the ground, the pattern would appear as a shifting mosaic (Bormann and Likens 1979; Remmert 1991) which may, if the patches are not too large relative to the size of the entire landscape, come to a steady state. Some landscapes may not produce an equilibrium distribution of patches (e.g. Romme 1982). Such patterns of patches and their dynamics can represent important sources of biodiversity in landscapes (Pickett and Thompson 1978; Foster 1980; Gilbert 1980). In many landscapes, successional species (Pickett 1976), certain desirable wild flowers (Little 1977; Menges 1990) and keystone mutualists (Gilbert 1980), among others, may depend to some extent on new or recently disturbed patches. Likewise, some heath communities, or prairies and savannas in moist climates (Jordan 1993) require disturbance among their defining parameters.

The requirement of certain desirable or rare species, or of interesting community types for the existence of disturbance in the landscape, points out an important way in which disturbance is ecologically significant. At the community level, disturbances create opportunities for some species and at the same time can disadvantage other species. Because community disturbance alters resources and environmental signals and regulators, it shifts the community niche space, or environmental determinants, at least temporarily. At the least, disturbance may temporarily disadvantage competitively superior species, giving less competitive species a respite that permits them to persist in the community (Denslow 1980; Pickett 1980). If the occurrence of disturbance is regular enough, it can, as stated above, act as a selection pressure and drive the specialization of species on the conditions it creates. Thus

some degree of fugitivity exists in many plant species that are denizens of even closed communities (Harper 1977).

What creates opportunity for some species almost always creates a limitation for others (e.g. Connell 1978). Only in the most physically extreme environments where a very few species are able to surmount the problems of making a living will this generalization not be expected to hold. Thus limitation and opportunity are opposite sides of the same coin. The principle of allocation (Cody 1966), which states that

organisms must allocate their limited stores of assimilated energy among mutually exclusive structures or functions, explains the generality of this relationship. It is such a powerful principle that it provides the basic foundation of many ecological theories and models that are used to predict species distribution in time and space (e.g. Tilman 1988).

In relating disturbance to biodiversity at the community level, it is important to know what species in a community are favoured, and which ones are disfavoured, by

Box 5.3-1: Thresholds in ecosystems.

In many of the world's biomes, ecosystems can exist in two or more alternative states which may differ with respect to their species composition, ecosystem functioning or ability to provide some ecosystem service. Each state may appear stable because modest perturbations have small or short-lived effects. Large perturbations, however, may shift the ecosystem from one state to another. Such state shifts can have important policy implications if ecosystems are transformed from desirable to undesirable states. (Perceptions of desirability or undesirability are value judgements related to societal goals or expectations, which are also subject to change through time.) If the undesirable state is stable, substantial policy changes or enormous resource commitments may be needed to restore the ecosystem to the desirable state.

Examples of alternative states are known from both terrestrial and aquatic ecosystems. Semi-arid grassland can remain productive as long as grazer density is modest (Noy-Meir 1975). When grazer density rises above a threshold, community composition changes rapidly and the ecosystem shifts rapidly to a state of degradation and low productivity. Once this occurs, the range will remain unproductive unless managers reduce grazer density substantially while the ecosystem recovers to a productive state. Forests subject to outbreaks of grazing insects also exhibit alternative states, in which outbreaks are either suppressed or spread rapidly (Ludwig *et al.* 1978). In lakes, changes in nutrient inputs and fish stocks can shift the ecosystem between states of good or poor water quality (Scheffer 1991; Carpenter 1992; Scheffer *et al.* 1993). Alternative states that differ in productivity may also exist in marine ecosystems (Steele and Henderson 1984; 1992; Knowlton 1992).

When exploitation of living resources is modest, the resource exists in a high-productivity state and yield is high (Clark 1976; Walters 1986). When exploitation rate rises above a threshold, the ecosystem shifts to a state of low productivity and yield remains low. Large and sustained reductions in exploitation are necessary to return the ecosystem to the high-productivity state, and significant economic losses can occur during the collapse and recovery stages. Adaptive management techniques can be used to detect and avoid thresholds (Walters 1986) when the political and social circumstances are favourable (Lee 1993).

Thresholds in the relationship between biodiversity and ecosystem functioning are hypothetical but plausible (see graph below). When biodiversity is relatively high, the ecosystem follows the limb of the curve labelled 'high'. The ecosystem process rate, which corresponds to production or some other ecosystem service, is relatively high but declines smoothly as biodiversity declines. When biodiversity decreases to level A, the ecosystem process rate falls abruptly to the limb of the curve labeled 'low'. Along this lower limb of the curve, the ecosystem process rate remains relatively low but increases slightly as biodiversity rises. To return the ecosystem to the state with high process rates, it is necessary to increase biodiversity above level B. If species have been lost permanently, restoration may be impossible. Species conservation maintains restoration options.

A threshold hypothesis is consistent with much of the evidence about ecological consequences of species' extinction (Ehrlich and Ehrlich 1981). However, there is considerable scientific disagreement about the particular shapes of the curves and the locations of the thresholds (Schulze and Mooney 1993). There is also uncertainty about whether particular species are crucial in determining the location of thresholds (Schindler 1990; Frost *et al.* 1994). At present, scientific capacities to predict thresholds in ecosystem behaviour are poorly developed.

Thresholds have significant implications for resource economics, ecosystem restoration and sustainability of ecosystem services. When ecosystems are driven across thresholds to undesirable states, losses can be long-lasting or even permanent. Costs of ecological restoration in economic, energy or material terms can rise steeply if ecosystems must be forced across a threshold to restore them. In some cases, restoration may simply be impractical. Where biodiversity is reduced by global extinctions, opportunities for restoration may be permanently lost.

Hypothetical relationship between an Ecosystem Process Rate and Biodiversity. Solid lines are alternative stable states, or relationships to which the ecosystem will return after modest perturbation. The dashed curve is a breakpoint. If the system is perturbed across the breakpoint, it will move to the other state. Points A and B are biodiversity thresholds. If the biodiversity is reduced below A, the ecosystem will collapse from the high state to the low state. To restore the ecosystem to the high state, the biodiversity must be raised above threshold B.

disturbance (Bazzaz 1983). Managers have long recognized contrasting categories of plant species, such as increasers and decreasers relative to grazing, and fire sensitive versus fire dependent species in certain forests, shrublands and grasslands. It would be inappropriate to argue that disturbance is good for all species in an assemblage. The insight that emerges from the last twenty years of new study, and synthesis of the insights of previous generations of ecologists, is that disturbance is ‘good’ for some species and ecological processes, not that it stimulates all natural or socially desirable species, ecological phenomena and systems. In other words, the role of disturbance is large in many systems, and biodiversity at various levels bears the stamp of disturbance. Successful management, restoration, conservation and sustainable development require that the role of disturbance in the target system and for critical processes, or for threatened and endangered species, be evaluated (Pickett *et al.* 1992). As a further elaboration of the analysis of the nature of disturbance, Carpenter (Box 5.3-1) discusses the importance of thresholds in perturbations to biodiversity as related to ecosystem processes.

5.3.1.4 Disturbance and management

Disturbance of ecosystems has implications for the maintenance and restoration of biodiversity at all hierarchical levels (McNaughton 1989; Walker 1989; Pickett and Parker 1994). The important role of both human agents (Mooney and Godron 1983; Naveh and Lieberman 1984) and natural agents of disturbance in a landscape is recognized here. Management involves the manipulation of existing systems, the restoration of a lost state (Hughes 1994), or the amelioration of an existing state of a system, while development, in the most positive sense, is the interpolation of anthropogenic and natural

systems. Every decision a manager makes (or neglects!) favours some species or ecological phenomena and disfavours others. This is the inexorable operation of the principle of allocation, and its resultant contrasts in the genetically determined strategies of organisms in the world as people now interact with it. No management (to use that word now to represent also restoration and sustainable development) can favour all species or states simultaneously. It is critical that management avoid damage to native and specialist species and their evolutionary potential. Management likewise must not neglect important processes and phenomena in landscapes, which is the *de facto* scale at which humans manage. In addition to understanding the biogeographic and evolutionary characteristics of the biota, successful management requires an understanding of the role of the disturbance regime in assembling the communities and ecosystems, and in driving ecosystem processes on which biodiversity depends. Management may sometimes have to maintain existing natural disturbance types, compensate for unavoidable natural disturbances, replace missing natural or pre-industrial human disturbances, or compensate for novel human stresses or reduced spatial extent of the system (Botkin 1991; Pickett *et al.* 1992). This list suggests that attention to the different kinds of disturbances, and the interactions among different anthropogenic and natural disturbances and stresses, is fundamental to successful and sustainable management, which must seek to maintain or recreate the multiplicity of opportunity that exists in the ‘patch dynamic’ natural world. The maintenance and importance of biodiversity are intertwined with these processes, and in order to use disturbance effectively, managers must know whether anthropogenic disturbances or stresses mimic the natural

ones that were important in the evolution or assembly of an ecological system.

Our understanding and use of the relationship between disturbance and biodiversity, rest on several key principles. Disturbance is the disruption of the structure of some specified ecological system. The most desirable way to specify the system is to provide a model that incorporates the system components, the connections among the components, and the scale of the system. Natural disturbance is an important and persistent component of the environments under which biodiversity evolved at the population and species levels and has been assembled at the community, ecosystem and landscape levels. Of course, the events that act as disturbance at each of these levels of organization differ in kind, frequency and scale. At some scales, apparently disruptive events become incorporated into the systems of interest, and the disturbance regime becomes a defining component of the larger system. In such situations disturbance must be maintained. Alternatively, if human management has prevented natural disturbance events, those events must be restored or substituted to permit the system to continue to exist. Thus, disturbance is a component of sustainability in some ecological systems and landscapes, but the type, intensity, frequency and scale must be properly applied if it is to remain a positive force in sustaining biodiversity.

5.3.2 Human-induced perturbations biodiversity

5.3.2.1 Introduction

Human perturbations affect biodiversity both directly and indirectly through changes in land and water use (Figure 5.3-1). Such changes have a direct impact through habitat destruction and over exploitation of resources such as occurs in overfishing and overgrazing, and an indirect impact through their effects on the composition of the atmosphere and the climate, both of which directly affect biodiversity. Changes in biodiversity in turn modify the functioning of populations, ecosystems and landscapes. Finally, these changes feed back into land-use patterns, atmospheric composition and climate, accelerating or decelerating the rate of global change and the impacts of human activities. Here we focus on the effects of land use, atmospheric composition, and climate on the different components of biodiversity whereas most of Sections 5 and 6 of the GBA analyse the effects of changes in biodiversity on ecosystem functioning.

Figure 5.3-1: Conceptual model of the effects of human-induced perturbations on biodiversity and ecosystem functioning. Changes in land and water use directly affect biodiversity and simultaneously modify the composition of the atmosphere and the climate. The alterations of land and water use include the overexploitation of resources such as in overfishing or overgrazing as well as drastic transformations such as the conversion of forests into croplands. Changes in climate and in the composition of the atmosphere also directly alter biodiversity.

5.3.2.2 Changes in land and water use

Forests, grasslands, savannahs, and deserts have been altered drastically by human activity. Over the last three centuries, forests have decreased by 1.2 billion ha or 19%, and grasslands by 560 million ha or 8% (Richards 1993). This is mainly the result of increase in croplands of 1.2 billion hectares and the growth of urban areas. The rate of land-use change is accelerating very rapidly, as is demonstrated by agricultural expansion which was greater during the period 1950–80 than during the entire 150-year period between 1700 and 1850 (Richards 1993). Land-use change also includes changes associated with the over exploitation of resources which are ubiquitous and more difficult to quantify. For example, livestock overstocking has resulted in severe degradation of rangelands (referred to as desertification), bush encroachment or brush invasion altering large areas of North America, Africa and Australia (Buffington and Herbel 1965; Walker *et al.* 1981; van Vegten 1983; Archer 1989).

Marine environments have been and still are being drastically modified by human action. Changes in water use are usually not reflected in qualitative shifts like those we observe in terrestrial environments but in steady and quantitative changes of their chemical, physical and biological properties. Anthropogenic additions of nutrients are most obvious in relatively shallow coastal seas such as the Baltic or the North Sea in Europe, or Puget Sound along the open coast of the state of Washington in North America (Jickells *et al.* 1993). As a result of the discharge of wastes from heavily populated and industrialized areas, the nutrient content of the oceans has increased significantly. For example, phosphate concentration in the Baltic increased by a factor of 3 in the period 1958–80 (Jickells *et al.* 1993). Increases in nutrient availability stimulate the growth of plankton which in turn consumes dissolved oxygen as it decomposes (Lancelot *et al.* 1987). Simultaneously with the increase in nutrient availability, dissolved oxygen in the deep waters of some parts of the Baltic Sea decreased from 3 ml/l at the beginning of the century to almost zero at present (Jickells *et al.* 1993). Besides pollution, humans also drastically alter marine environments by over-exploiting resources. Overfishing has resulted in the elimination of substocks of herring, cod, ocean perch and salmon in several regions of the world (Ludwig *et al.* 1993).

Changes in land use are the major causes of habitat destruction and fragmentation, and these in turn are the major causes of recent extinctions, and constitute a major threat to biological diversity (WCMC 1992; Skole and Tucker 1993). A clear indication of the importance of habitat destruction in accounting for changes in biological diversity is that one way of estimating current and predicted losses of species diversity is based solely on combining information on current and projected

deforestation rates with information on species richness per unit area in tropical forests (Ehrlich and Wilson 1991; see also Section 4.4). The assumption that global terrestrial species extinction rates can be assessed from tropical forest extinction rates is justified on the assumption that most terrestrial species occur in tropical moist forests. Independent exercises using different approaches have estimated extinction rates to be of the same order of magnitude as those estimates based on species–area relations and the rate of habitat loss (Smith *et al.* 1993; Heywood *et al.* 1994).

Although drastic changes in land use such as large-scale transformations of forests into grasslands or grasslands into croplands usually result in reductions in global species diversity, more subtle human-induced changes sometimes increase local species diversity. For example, some grasslands that evolved under low grazing pressure have shown increases in species diversity as a result of the introduction of livestock and the consequent increase in grazing intensity (Sala *et al.* 1986; Milchunas *et al.* 1988). This pattern is accounted for mainly by the introduction of alien species better adapted to grazing conditions, without the disappearance of native grasses. Further increases in grazing intensity have reduced diversity as introduced grazing-tolerant species have become dominant. Human activity is mostly neutral or negative with respect to genetic or species diversity. Only recently – by means of biotechnology – have humans increased diversity. However, at the community and landscape levels human activity may either increase or decrease diversity. Naveh (1971) suggested that human-induced livestock grazing has increased plant, community and landscape level diversity in the Mediterranean Basin.

5.3.2.3 Changes in atmospheric composition

Recent changes in the composition of the atmosphere are a clear indication of the major disruption of biogeochemical cycles that have occurred as a result of human activities (Schlesinger 1991). First, scientists pointed out the perturbations of the carbon cycle and the resulting sharp increase in the concentration of carbon dioxide in the atmosphere (Keeling 1986). Next in importance is the disruption of the nitrogen cycle as evidenced by the magnitude of human-induced nitrogen fixation, the increase in nitrous oxide emissions, and the high values of nitrogen deposition over most of the developed world (Matson and Vitousek 1990; Vitousek 1994). These alterations of biogeochemical cycles have always resulted in ecosystem enrichment and, in most ecosystems, nutrient enrichment results in a sharp reduction in species diversity. Experimental fertilization of shortgrass steppe, tallgrass prairie, tundra and deciduous forest has always resulted in decreases in plant species richness (Lauenroth *et al.* 1978; Schulze 1989; Tilman 1993).

The increase in atmospheric CO₂, and the corresponding CO₂ fertilization effect, results in an ecosystem carbon enrichment which is modulated by nutrient and water availability (Mooney *et al.* 1991). Carbon enrichment can be expected to have effects on biodiversity similar to those that have been demonstrated for the enrichment of ecosystems with nutrients. Because our ability to perform CO₂ enhancement experiments in whole ecosystems is relatively recent, there is no experimental evidence to assess the effect of CO₂ fertilization on biodiversity. Experiments under controlled environmental conditions support the hypothesis that CO₂ enhancement changes plant–plant interactions, and alters the competitive balance among species, which might lead to a decrease in plant species diversity. Elevated CO₂ field experiments based on open-topped chambers showed a distinction between the response of C3 and C4 species in a salt-marsh (Curtis *et al.* 1989). Morse and Bazzaz (1994) also exposed two species with different photosynthetic pathways to elevated CO₂ concentrations and found that the C3 species (*Abutilon theophrasti*) showed a larger response than the C4 species (*Amaranthus retroflexus*). Based upon experiments under controlled environmental conditions, Polley *et al.* (1994) suggested that the invasion of the C4 grasslands in the southwestern United States by woody C3 mesquite (*Prosopis glandulosa*) during the past 150 years can be related to the observed 27% rise in atmospheric CO₂. Species-specific differences among CO₂ responses of forest trees have been reported for temperate zones (Williams *et al.* 1986; Norby *et al.* 1992) although not for tropical ecosystems (Körner and Arnone 1992). Phillips and Gentry (1994) speculated that increased CO₂ may favour vine growth in tropical forests, which may explain the observed increase in tree mortality.

5.3.2.4 Climate change

The indirect effects of changes in the composition of the atmosphere and changes in land-use patterns occur via changes in climate. Changes in land-use and atmospheric composition have already been detected and will affect ecosystems and humans sooner than changes in climate. However, climate change has been the first global change phenomenon to attract the attention of scientists and policy-makers. Scientists agree that an increase in the atmospheric concentration of greenhouse gases such as CO₂ and methane will result in an increase in global temperature and a change in the global distribution of precipitation. Current uncertainties are related to the geographical patterns of those changes and the speed with which they will occur (Mitchell *et al.* 1990). Predicted changes in climate for a doubling of atmospheric CO₂ are quite significant for most regions in the world. Models that relate average climatic variables to the distribution of vegetation types are ideal tools for assessing the potential effect of climate change

Box 5.3-2: Management for sustainable biodiversity.

To manage and exploit the environment effectively, and sustainably, scientific information must be translated into management plans and actions. However, promoting the wise use of ecological concepts in managing the Earth's biodiversity is neither simple nor straightforward. It requires not only specific scientific skills, but also considerable leadership qualities in co-ordination, integration and advocacy. On the other hand, the challenges and opportunities for a decisive involvement of the ecological sciences in environmental management are greater than ever, given that the Convention on Biological Diversity and the *Agenda 21* document signed at the UNCED Rio summit in 1992 provide ample political support at the highest level. How do we translate ecological research into management? Here, some key aspects of the research/management interface are discussed.

1. *The available options are limited.* The options available to managers are restricted by practical feasibility, environmental acceptability, economic desirability, and in many cases political advantage (Saunders and Burbidge 1988). Time is a key constraint. Decisions need to be made within a given (and usually short) time horizon, and typically with only incomplete information available. In the case of biodiversity, for example, the rate of loss of both species and habitats is growing exponentially, leaving less and less time for detailed, long-term studies (Meadows *et al.* 1992).

2. *Management for sustainable biodiversity must be based on the precautionary principle.* The precautionary principle, and the associated notion of reserved rationality (Perrings 1991; see Section 12), apply to those decision-making problems in which both the level of fundamental uncertainty and the potential costs are high. Examples include the use of environmental resources in novel ways and at high levels of magnitude. Both principles imply the need to proceed cautiously to safeguard against the possibility of unexpectedly severe future costs when there is ignorance as to the probability distribution of the magnitude of the negative impacts. In other words, when dealing with decisions that have the potential to destroy crucial life-supporting systems, it is prudent to have some margin for error (on the conservative side) as one learns the outcomes of a given management policy. It is also prudent to make allowances for the potential, although uncertain, future losses associated with the resulting use of environmental resources and services. By necessity, the precautionary principle implies a high value-driven judgment about the responsibility borne by present generations toward future generations (Perrings 1991). Therefore, and acknowledging that at present we do not have all the answers we need, the only prudent policy to assume today is that while there is clearly redundancy in the role of species in delivering some services, there may also be an extinction threshold which, if crossed, will result in unacceptable deterioration of ecosystems services (see 5.1). Accordingly, the precautionary principle indicates that extreme care should be taken before labelling any species as 'redundant'. Since the precautionary principle entails a cost for human societies, decisions need to be made about how much the precautionary principle would have to be stretched or how much insurance different societies can afford to buy. These kinds of decisions will be greatly aided by a better understanding of the relationship between biodiversity and ecosystem functioning.

3. *The relationship between science and management is a two-way process.* There is no such a thing as a definite, prescription regarding environmental management. Management is a continuous, dynamic and interactive process involving research, implementation and monitoring. Therefore, a continuous feedback between researchers, managers and users is clearly necessary. Accordingly, the following basic steps are required in a well planned project: (a) planning and developing goal-orientated research, (b) dissemination of results, (c) implementation of management practices and policies, and (d) monitoring and feedback.

An important component of this two-way process is the adaptive management approach, i.e. using management practices as a research tool to obtain information and insight to fine-tune management practices. Use of management as a research tool has considerable potential, providing access to semi-experimental situations at a scale and degree of realism well beyond the possibilities of 'traditional' experiments (Holling 1978). Furthermore, the management project itself can be used as an experimental probe as, for example, when manipulating grazing pressure as a way of understanding vegetation dynamics in savannas or grasslands. The adaptive management approach is particularly useful when decisions need to be made in situations where data are incomplete and uncertainty is great, requiring an ongoing, flexible, and sometimes opportunistic process. A particularly important challenge for researchers on the functional role of biodiversity is the need to develop sustainable management models for each of the Earth's biomes, in which both ecological services and human use are made compatible (see for example Milton *et al.* 1994 for a discussion on savannas). Furthermore, involvement in real-world situations favours interdisciplinary work, while providing a better insight into the constellation of factors (biological, economic and social) affecting the system under management.

under equilibrium conditions. One of the earliest models of this kind is the one developed by Holdridge (1947) (see Section 2.3). Analysis of the distribution of vegetation in equilibrium with the new climatic conditions showed big shifts of vegetation types under a double CO₂ climate (Emanuel *et al.* 1985; Kramer and Leemans 1993). The main result is a poleward shift of vegetation patterns. Approximately 30% of the vegetation of the Earth will experience a shift as a result of the predicted climate change. Although the climate change is expected to be significant, the major threat for biodiversity is the speed with which this change will occur. Changes of the magnitude predicted for a doubling of CO₂ have occurred during the Earth's climate shift from glacial to interglacial periods. However, while these changes occurred over millennia, the expected human-induced changes will occur in less than a century (Watson *et al.* 1990). The rapid change in climatic conditions will hamper the ability of individual species to migrate to regions with climatic conditions similar to those of the present. Moreover, in some cases such as the Arctic, the area favourable for the survival of an individual species will be largely reduced. The reductions of suitable areas for a large number of species, and a change in climate faster than the migration rate of most species, is certain to result in a drastic reduction of global species diversity.

5.3.2.5 Conclusions

Human-induced perturbations differ quantitatively and qualitatively from natural perturbations. Humans have increased the frequency and severity of natural disturbances to the extent that their impact is now greater than that of most natural ones (Likens 1991). The duration of human disturbances is also usually much longer, and the frequencies are much higher, than natural ones (Reiners 1983; Woodwell 1983). Among the major threats to species diversity are the qualitatively new kind of disturbances for which no specific adaptations have yet evolved. Humans have synthesized new chemical substances which have reduced the stratospheric ozone layer at higher latitudes in the Southern Hemisphere as well as at mid-latitudes (Farman *et al.* 1985; Stolarski *et al.* 1991). A reduction in the ozone layer allows increased quantities of short wave radiation (UV) to penetrate through the atmosphere. There is evidence that increased UV results in major negative effects on primary producers as well as on the next trophic level (Caldwell *et al.* 1989; Smith *et al.* 1992; Bothwell *et al.* 1994). Equally new is the ability of humans to exchange floras and faunas which has resulted in rapid and major invasions of exotic plant and animal species (Drake *et al.* 1989). Increases of some insect, plant pathogen and weed pests may be associated with the increase in CO₂ and temperature (Pimentel *et al.* 1992).

All the human-induced perturbations described here result in reductions of global species and genetic diversity, although some human manipulations may result in local increases in genetic, species, community, ecosystem and landscape diversity. Human-induced perturbations under the term 'global change' directly affect ecosystems, and humans who depend on ecosystem services (Ehrlich and Mooney 1983). Global change reduces species diversity which in turn (as described in Sections 5 and 6) may affect ecosystem functioning. The truly irreversible nature of the loss of genetic and species diversity is what it makes it so important for humans (Vitousek 1994). In contrast, the changes in atmospheric composition and climate and to a large extent land use are reversible. Reducing of 'human forcing' will result in a slow return of the atmosphere and the climate to approximately original conditions. In contrast, the loss of population and species diversity is permanent. The combination of genes that results in a variety of morphologies and behaviours will be lost for millions of years or even forever. The issue of how to satisfy the increasing demands of human societies for goods and services and simultaneously to ameliorate the rate of species and populations loss, is discussed in Box 5.3-2.

5.4 Conclusions

5.4.1 Background

Fundamentally, we wish to answer the simple question: Does biodiversity matter in the functioning of ecological systems? This question should be addressed with respect to the four major principles introduced in Section 5.0: (1) the levels of biological and ecological organization and their interactions, (2) the numbers of different biological units within each level, (3) the influence and degree of similarity in the traits or roles that biological and ecological units within each level play, and (4) the spatial configuration of the units within any level. We have thus summarized the conclusions of the chapters in Section 5 with respect to these four principles. We then proceed with a synthesis of these conclusions with respect to the influence of human actions and implications for management. The summary and synthesis take the form of several simple questions.

5.4.2 What are the influences of genetic diversity on ecosystem functioning?

Ehrlich (5.1) and Templeton (5.2.1) both point out that intraspecific genetic variation can be, and has been, exploited to change quantitative aspects of ecosystem functioning, e.g. by increasing crop yields. In addition, intraspecific genetic variability confers some adaptive capability to those species, and thus increases the possibility that their functional roles can continue to be expressed in ecosystems that are undergoing environmental variability or stress. There is very little information on whether the genetic similarity of populations influences ecosystem functioning. Templeton (5.2.1) points out that

the phenomenon of local adaptation of populations to their environment is well known, and thus the spatial configuration of genetic variability might be important. Reintroduction of species to areas from which they have been lost is generally most successful if the reintroduced individuals are from populations that originated close to the original area. It is not unreasonable to suppose that there are ramifications of these observations for ecosystem functioning, but direct experimental evidence or observations are lacking.

5.4.3 What are the influences of species diversity in ecosystem functioning?

In many cases, species clearly matter. This is primarily because the species plays an important and unique role in its ecosystem. Removal or addition of the species results in a dramatic and obvious change in the other species in the ecosystem or in a key ecosystem process. The evidence for this conclusion is compelling; the number of examples is increasing as more systems are examined; and these keystone species (Chapin *et al.*, 5.2.2) have been reported from a wide range of ecosystem types. However, in spite of the widespread existence of the phenomenon, no species characteristics have emerged that allow prediction of which species will play keystone roles. In fact, some small or cryptic species have been found to play a keystone role.

In many other cases, however, there appears to be substantial overlap among species with respect to their functional roles. Their removal or addition appears to have little demonstrable effect either on other species or on an ecosystem process. Other species compensate for the absence of the target species, at least in the short term. However, it is not known with certainty if all functions of the species in question are compensated for (in fact, it is rarely understood what the full range of functions is for each species). For this reason, it is probably inappropriate to say that species are 'redundant'.

Ecosystems with greater overlap among species with respect to any particular process will be more resistant to change than otherwise comparable systems characterized by little compensatory potential. This stability is predicted to be a direct result of the fact that species that overlap with respect to a particular function probably differ with respect to their responses to environmental changes such as temperature, salinity, ultraviolet radiation (UV-B), or exposure to toxic compounds. Compensatory overlap is thus suggested to provide 'insurance' in the sense that key functions are more likely to continue despite changes that result in the loss of some species. There is some evidence for this prediction, but it is a very difficult phenomenon to demonstrate. There is no evidence that contradicts the predictions. This is an area where further research is needed.

The above conclusions focus on particular traits of species and the extent to which the traits are unique to a

species or not. A separate question of importance is whether the number of species *per se*, apart from their specific traits, has a strong influence on ecosystem properties. The number of species in an ecosystem is functionally important, independent of the traits of the species, for two reasons: (1) more species generally increase the rate or efficiency of resource capture under steady-state conditions, and (2) more species provide insurance against large changes in ecosystem processes in response to disturbance or environmental change (Chapin *et al.*, 5.2.2).

The spatial structure of species populations within ecosystems has influences on their interactions, their diversity and abundance, and therefore on ecosystem-level processes (Harrison, 5.2.3). Changes in spatial structure, especially fragmentation of habitats, act differentially on different kinds of organisms, depending in part on body size, trophic level, life-history characteristics and successional stage. Fragmentation reduces the diversity of native species in their natural habitats and the types of species most likely to be lost are those with the highest rates of local extinction on small habitat patches (e.g. top predators and other species with large body sizes and large area requirements). Also likely to be lost are species with lower abilities to disperse and colonize habitat patches. Species likely to survive fragmentation will be those best adapted to patchy and frequently disturbed environments, especially early successional and easily dispersed species.

Fragmentation is thus expected to result in ecosystems dominated by 'weedy' species characterized by short life-span, rapid growth rate, and high reproductive and dispersal capacity. This, in turn, is expected to result in numerous ecosystem-level consequences: faster turnover and leakier systems with respect to nutrients, nitrogen, and carbon; higher litter quality and therefore faster decomposition rates; simpler spatial structure; less overall protection from herbivory; and different kinds of chemical defences against herbivory, tending to low molecular weight compounds.

Thus, the assessment is revealing that in many cases 'species matter' in a fashion that can be demonstrated; in others, species appear to be sufficiently similar to other species with respect to their functional roles that their loss should have no immediate consequences, but unequivocal demonstration that they will or will not 'matter' over a longer period of time is difficult and unlikely to occur. This does not mean that every single species matters in every single situation. There are certainly examples where species have been lost and there has been no demonstrable change to the ecosystem's functioning. It is difficult to say, however, that no change occurred; the evidence available does suggest that there was no catastrophic change.

5.4.4 What are the influences of landscape diversity on ecosystem functioning?

At a landscape or regional scale, the key processes to understand are those that regulate the movement of materials (e.g. nutrients, water, trace gases, etc.), energy fluxes, and dispersal of organisms among the constituent ecosystems, and between the ecosystems and the atmosphere and hydrosphere (Burke and Lauenroth, 5.2.4). The number of different types of ecosystems on a landscape has obvious effects on the total functioning of the landscape. Those ecosystems that cover large areas obviously have important roles; however, some ecosystems on a landscape have functional importance out of proportion to their abundance (Burke and Lauenroth, 5.2.4). This is true of riparian areas and wetlands, particularly in respect of their capabilities to purify water before it reaches streams and rivers, and also for marine systems such as coral reefs, mangroves and kelp forests.

Because of climatic, topographic and geological variation; historical differences; and disturbance frequency, severity and extent (Pickett, 5.3.1; Burke and Lauenroth, 5.2.4), the arrangement of ecosystems on the landscape can be extremely complex, and this complexity affects the total functioning of the landscape. Many of the transfers across landscapes are the result of directional processes, such as wind and water flow, and therefore the total effect of the processes in a region may depend critically on the actual spatial arrangement of the ecosystems, and how that array is orientated with respect to these abiotic factors. The fragmentation of habitat associated with human activities can alter landscape/regional diversity by affecting the spatial patterns of ecosystems on the landscape, by fragmenting the landscape, in effect creating new, disturbed areas, and/or by decreasing the total area of different ecosystems on the landscape. Each of these effects may have characteristic results for different types of species, and thus for ecosystem processes. For example, the spatial pattern of the fragmentation results in the provision of dispersal corridors for some organisms, but reductions in available habitat and opportunities for dispersal and migration for others, and can have a great effect both on overall levels of biodiversity and on ecosystem functioning across the landscape.

5.4.5 What are the human influences on ecosystem functioning?

Human-induced changes in biodiversity are characterized by their increased frequency (rate of change), severity (magnitude of change), and increased spatial extent (Sala, 5.3.2). At a local scale, human activities can have negative (local population eradication), neutral (sustainable harvesting), or even positive (e.g. increase in the number of landscape units) effects on biodiversity. When viewed at a global scale, though, human activities reduce biodiversity

at genetic and species levels, and species' extinctions are completely irreversible. In addition, human activities can create environmental changes for which biota are not at all adapted, for example increased surface UV-B flux due to reduction in stratospheric ozone, or the proliferation of novel, but extremely toxic compounds in the environment.

Extractive activities, such as agriculture and forestry, tend to increase the fluxes of materials in ecosystems across a landscape, often leading to increased losses of nutrients, increased surface water flow, increased sedimentation in streams and rivers, and long-term reductions in soil carbon and soil fertility. These activities clearly affect landscape functioning through their effect on the diversity of ecosystems within a landscape. Other human activities, such as the construction of dams for water control, have very different effects at landscape scale, often resulting in the concentration and immobilization of nutrients and sediment in particular parts of the landscape. Still others, such as fire control in forests, have the effect of dramatically changing the disturbance regime, resulting in widespread changes in landscape functioning.

5.4.6 What are the management implications for goods and services?

To manage and exploit the environment effectively and sustainably, scientific information needs to be translated into management plans and actions. However, there is great difficulty in managing to provide goods and services simultaneously while maintaining diversity at prudent, sustainable levels. Several important principles can be used to guide the implications for management: (1) practical constraints on feasibility, environmental acceptability and economic desirability must be clearly understood; (2) a goal-orientated approach must be applied that recognizes that there are always multiple objectives in any management scenario; (3) an iterative process, analogous to that of adaptive management in forestry, should be employed in order to integrate the knowledge

gained from earlier management decisions into a continually improving management scheme; and (4) when uncertainty about the resource base or the knowledge base is predominant, the precautionary principle should be employed, thus avoiding whenever possible decisions that close off future options.

5.4.7 Summary

Section 5 has laid out in broad detail the important concepts governing the study of the relationships between biodiversity and ecosystem functioning. The importance of considering biodiversity at multiple levels of organization is emphasized, as is the degree of influence and similarity in traits, and the spatial arrangement of biological units within any level of organization. Redundancy of function of species within ecosystems and ecosystems within landscapes cannot be assumed: indeed, some species and ecosystems have unique functional roles that are significant out of all proportion to their abundance. The main consequence of diversity at all levels seems to lie in the degree of adaptive insurance it provides for the maintenance of ecosystem processes against environmental variation and/or stress.

The human influences on biodiversity and ecosystem functioning have largely taken the form of rapid, large, and frequent changes in land and resource use, increased frequency of biotic invasions, reductions in species numbers, creation of novel stresses, and the potential for change in the climate system. Although disturbance is a critical element controlling the composition and functioning of ecosystems, human influences have increased its pace and extent well beyond previously known levels. The major implications for the continued provision of ecological goods and services are to create and use management strategies in an adaptive fashion, to ensure that sufficient resources are maintained in the system to provide resilience, and to be cautious about making potentially irreversible decisions.

EXECUTIVE SUMMARY

1. Ecosystems provide services to humans that are crucial for their well-being. These services are not widely recognized, nor are they properly valued in economic, or even social terms.
 2. The Earth is covered by a myriad distinctive ecosystems all of which are increasingly impacted by human activity.
 3. Human-driven perturbations to ecosystems are altering their structure, depleting stores of resources that fuel productivity, disconnecting populations and disrupting species interdependencies.
 4. The accidental introduction of species can have major, and often detrimental, impacts on the functioning of ecosystems. Successful establishment of invaders is greatest in those systems that are biotically simple, such as islands, and those that have been disturbed by human activity. The potential success of a particular invading species is difficult to predict but its ecosystem impact depends on whether it utilizes or produces a resource unique to its new habitat.
 5. All ecosystem services are affected to one degree or another by reductions in diversity. This fact follows simply from the greater resource capture, i.e. of energy, water, nutrients, sediments, of diverse systems compared to simple systems. However, depending on the time dimension and functional types present, the exact relationship between diversity and function will vary.
 6. Certain ecosystems, such as arid and arctic ecosystems, and those found on islands, appear particularly vulnerable to human disruptions and hence alteration of their functioning. These sensitive systems all have low representation of key functional types (organisms that share a common role).
 7. The types of connection among ecosystems within a landscape greatly influence the exchange of nutrients, water, sediments and genetic material. Ecosystems, and the services they provide, must be considered in a total landscape context and in some cases even on an intercontinental basis.
 8. As society exerts ever greater control and management of the ecosystems of the world, great care must be taken to ensure their sustainability, which is due in large part to the buffering capacity provided by biotic complexity.
-

6.0 Introduction

6.0.1 Background

In this section, the general principles outlined in Section 5 are used to assess our current knowledge of the ecosystem-level consequences of human-induced changes in biodiversity. We provide separate assessments for a selection of the major biomes of the world because the human impacts on biodiversity and the associated ecosystem consequences differ among biomes and because decision-makers will require different information for each. Our sample includes freshwater, marine and terrestrial systems that represent a significant portion of the ecosystems on Earth.

6.0.2 Biome essays and ecosystem processes

For each of the 15 biomes surveyed, the authors provide information on the consequences of human-induced changes in biodiversity for seven ecosystem processes and/or properties:

- Productive capacity and biomass
- Soil structure, nutrients and decomposition
- Water distribution, balance and quality
- Atmospheric properties and feedbacks
- Landscape and waterscape structure
- Biotic linkages/species interactions
- Microbial activity

These topics involve key ecosystem processes, such as carbon, water and nutrient cycling. They also recognize the importance of higher levels of integration in ecological systems; interactions between the Earth's surface and atmospheric properties; biotic linkages, because they result in the provision of many essential ecosystem services; and microbial activity, which fuels many ecosystem-level processes. More extensive discussions of these points with respect to each ecosystem can be found in the forthcoming SCOPE volume (Mooney *et al.* 1996).

The biome essays provide biome-specific information on (a) the drivers of change in biodiversity, (b) the impact of these drivers on biodiversity at multiple levels, and (c) the ecosystem consequences of these changes in biodiversity. For example, as outlined in the coral reef essay (6.1.10), a major driver of change in these systems is overfishing by the growing human populations that inhabit the adjacent coastlines. The impact of this driver on biodiversity is to reduce greatly the abundance and diversity of algae-grazing fishes. A significant ecosystem consequence of this change is the transformation of reefs from coral-dominated to algae-dominated systems. These changes have direct and immediate feedbacks to people who depend on coral reefs: in addition to buffering coastal environments from storms, coral reefs provide an array of highly specific taxa that are important in commercial and subsistence harvesting.

6.0.3 Cross-biome comparisons and syntheses

After considering each of the 15 biomes in our sample, the authors generate cross-biome comparisons of the ecosystem consequences of human-induced impacts on biodiversity. These seven essays provide comparative analyses of the functional consequences of an increasingly modified world. We then synthesize the findings of the individual biome essays and the cross-biome comparisons to derive our final conclusions.

We have attempted throughout to provide a synthesis of our conclusions that is in a form accessible to both policy-making and scientific communities. Inevitably, our current ability to address all the questions for which one would like answers is limited in some cases. However, the hope is that future efforts will benefit from an articulation of these questions and from knowing where the gaps in scientific knowledge exist.

6.1 Biome essays

6.1.1 Arctic and alpine systems

6.1.1.1 Introduction

Arctic and alpine ecosystems are cold-dominated ecosystems lacking trees. These ecosystems occupy about 8% of the terrestrial surface of the globe (5% Arctic, 3% alpine) but support only about 4% of the global flora (1500 Arctic species, 10 000 alpine species) and fauna. Species diversity of plants and animals in Arctic and alpine regions declines with increasing latitude and altitude, but genetic diversity within species appears unrelated to climatic severity. Within both regions species diversity of plants and animals is concentrated in areas of high vertical relief, lacking a well-developed organic mat. The vast expanses of peat-covered landscape in the Arctic and in level terrain in alpine regions have very few species (generally <10 vascular plant species per m²), and these species have a widespread geographic distribution. Landscape diversity strongly influences terrestrial-aquatic exchanges, particularly in permafrost-dominated Arctic terrain, where water and nutrients flow laterally among ecosystems (Kling 1995).

6.1.1.2 Productive capacity, biomass, decomposition and nutrient cycling

Human impacts on biodiversity. Other than the direct impacts of land use, the most profound human impacts result from activities outside Arctic and alpine ecosystems, such as CO₂-induced climatic change, which may increase

reproductive output and growth in the high Arctic (Wookey *et al.* 1993) and cause major changes in growth-form composition in the low Arctic (Chapin *et al.* in press) and alpine regions. CO₂ has little direct effect on Arctic or alpine plant growth (Tissue and Oechel 1987) or ecosystem CO₂ flux (Oechel *et al.* 1994; Körner *et al.* 1995). Arctic haze derived from pollutants produced at low latitudes could reduce the cover of mosses and lichens (Lechowicz 1987), which provide the major insulating layer protecting permafrost integrity (Tenhunen *et al.* 1992).

Ecosystem consequences of impacts. In the Arctic, changes in the relative abundance of current species generally have little direct effect on productivity and nutrient cycling because reduced abundance of some species is balanced by increased abundance of others (Chapin and Shaver 1985). Overall productivity is strongly constrained by climate and nutrient supply, so that energy and nutrient cycling are relatively insensitive to large changes in relative abundance of species and growth forms. However, these changes in species composition can have long-term effects on nutrient cycling and productivity through changes in litter quality and rates of decomposition (Shaver *et al.* 1995) or nitrogen inputs by lichens and the blue-green algae associated with mosses. Climatic warming increases the abundance of shrubs which have higher litter quality than the mosses they replace (Chapin *et al.*, in press). Similarly, reduction in moss cover resulting from pollutant inputs could increase energy inputs to soil and soil temperature (Tenhunen *et al.* 1992; Zimov *et al.* 1993a). Warmer soils enhance decomposition and the nutrient supply to vascular plants (Nadelhoffer *et al.* 1991). Lichens, which are important both as a source of N fixation and as winter food for caribou, are particularly sensitive to shading by shrubs (Chapin *et al.* in press) and to air pollutants (Lechowicz 1987). Changes in grazing can also modify the diversity of plant functional groups. For example, large mammalian browsers increase in response to increased shrub growth. In the boreal forest, these browsers speed the rate of succession by removing highly palatable species, leaving species with lower litter quality and associated declines in decomposition and nitrogen mineralization (Pastor *et al.* 1993). Thus, the major effects of climatic warming may operate primarily through changes in composition of plant and animal communities and litter-quality feedbacks to nutrient supply rather than directly on the productive capacity of vegetation.

6.1.1.3 Soil structure and nutrient pools

Human impacts on biodiversity. Soil structure and nutrient pools are most strongly dependent on human activities that influence long-term ecosystem persistence. In both the Arctic and the alpine, human disturbance that destabilizes soils (e.g. tourist developments in the alpine and use of tracked vehicles in the arctic) increases the

physical interactions among landscape units. For example, destabilization of slopes in the alpine causes down-slope delivery of avalanche debris. In the Arctic, permafrost degradation associated with mining and oil development expands beyond the initial zone of disturbance due to heating of adjacent soils, melting of ice, impoundment of water, and slumping of soils (Billings 1973; Walker *et al.* 1987).

Ecosystem consequences of impacts. This shift in landscape structure from mesic to wet tundra results in lower productivity, lower decomposition and greater carbon storage than does the original tundra from which it was formed (Chapin *et al.* 1980; Oechel and Billings 1992). Some of the biologically richest ecosystems in the lower alpine zone in Eurasia have developed over millennia of traditional cattle grazing or mowing but are losing species with the current abandonment of lands. This loss of diversity affects slope stability and drainage. In both Arctic and alpine ecosystems, return to the original ecosystem type following soil destabilization can require hundreds to thousands of years.

6.1.1.4 Water distribution, balance and quality

Human impacts on biodiversity. Human impacts on ecosystem integrity and landscape diversity (see above) strongly influence water quality and distribution. Destabilization of alpine slopes reduces plant cover and increases the quantity and seasonal variation in runoff to rivers, presumably affecting aquatic community structure and trophic dynamics. In the Arctic, human-induced melting of permafrost can lead to siltation of rivers and to formation of new ponds (Walker *et al.* 1987).

Ecosystem consequences of impacts. Even small anthropogenic nitrogen or phosphorus additions to Arctic lakes and streams substantially increase algal and fish production, increase production by benthic mosses, and greatly alter the species composition of zooplankton (lakes) and insect grazers (streams), shifting from a detritus-based to an algae-based food web (Peterson *et al.* 1993).

6.1.1.5 Feedbacks to atmospheric properties

Human impacts on biodiversity. Recent climatic warming is already causing upward migration of alpine species (Grabherr *et al.* 1994) and is predicted to cause northward and up-slope movement of treelines (D'Arrigo *et al.* 1987; Briffa *et al.* 1990). This represents a major change in distribution and diversity of species and functional groups in cold-dominated ecosystems. If climatic warming leads to drier soils, this would change landscape diversity, which at present is largely determined by topography and soil water movement.

Ecosystem consequences of impacts. Northward and upward movement of treelines would substantially increase annual energy absorption by northern ecosystems by

masking snow and reducing albedo. This would act as a positive feedback to regional climatic warming, an effect that would be most pronounced at high latitudes, but could extend to the tropics (Bonan *et al.* 1992). The current net CO₂ efflux observed in Arctic ecosystems may depend directly on soil drying (Oechel *et al.* 1993) in the wet Arctic of North America (with diversity playing little role), but the increased CO₂ efflux in the drier Russian Arctic could reflect a reduction in cover of pollutant-sensitive mosses, whose insulative properties govern the soil temperature regime (Zimov *et al.* 1993b). Arctic wetlands and associated loess sediments are large terrestrial sources of methane (Reeburgh and Whalen 1992; Fukuda 1994), and changes in landscape diversity, as a result of soil drying, could reduce methane efflux. Changes in the abundance or species composition of sedges, which transport most methane from Arctic soils to the atmosphere (Torn and Chapin 1993), could alter fluxes of this greenhouse gas and, therefore, the role of methane in atmospheric warming (Whalen and Reeburgh 1992).

6.1.1.6 Landscape and waterscape structure

Human impacts on biodiversity. Human agricultural (alpine) and industrial (arctic) developments have substantially altered landscape structure and diversity. For example, in the Arctic, the building of roads and pipelines has altered patterns of water drainage, and the relative abundance of waterlogged and well-drained soils. In the alpine regions, the construction of ski runs has smoothed the landscape and introduced new plant communities. Such land-use change can alter hydroelectric yield. These indirect impacts of energy development are many times larger than the direct impact of development (Walker *et al.* 1987).

Ecosystem consequences of impacts. For ecosystem consequences, see the above sections on soil structure and water distribution.

6.1.1.7 Biotic linkages and species interactions

Human impacts on biodiversity. Increasing demand by non-Arctic people for Arctic animal products, combined with increasing hunting efficiency, has resulted in a greater human harvest of marine and terrestrial mammals, in many cases causing or contributing to population declines. This is often combined with changes in human social structure which might otherwise have placed limits on the exploitation of these animal resources (Young and Chapin 1995). In addition, human-induced climatic warming is altering the competitive balance and diversity of plant species within the Arctic (see productive capacity) and could decouple the phenology of plants and their pollinators, leading to elimination of plant species that may have important ecosystem effects (Inouye and McGuire 1991).

Ecosystem consequences of impacts. In cases where animals (e.g. sea otters) are keystone predators, over-

hunting produces effects that propagate through the entire ecosystem. Human hunting of the Pleistocene megafauna may have triggered the change from grass-dominated steppe to less productive moss-dominated tundra at the end of the Pleistocene (Zimov *et al.* 1995). Changes in abundance of reindeer or herding practices in Russia and Scandinavia greatly influence lichen cover and, therefore, the vegetation structure and productivity of these landscapes (Andreev 1978). Geese and other waterfowl determine productivity, nitrogen input and cycling rates, and disturbance regimes, in Arctic salt marshes (Jefferies and Bryant 1995), and recent changes in the abundance of geese have totally altered the structure and dynamics of these coastal ecosystems. Little is known about the ecosystem impacts of possible changes in pollinator abundances. Insect-pollinated species are concentrated in areas of vertical relief, which contribute little to carbon storage or methane flux but are important in slope stability.

6.1.1.8 Microbial activities

Human impacts on biodiversity. Human impacts on microbial activity are mediated primarily by changes in species composition and litter quality (see productive capacity) and secondarily by the introduction of contaminants from oil spills and pollution.

Ecosystem consequences of impacts. Most Arctic and alpine ecosystems have a similar spectrum of enzymatic potentials to degrade common substrates such as lignin, cellulose and proteins, despite large differences in litter chemical composition (Schimel 1995). Ecosystems do differ, however, in their capacity to produce or consume methane, petroleum products and many anthropogenic pollutants. Changes in microbial diversity are thus more likely to be important in the production and degradation of unusual substrates than in the normal processing of plant litter and soil organic matter.

6.1.1.9 Summary and relevance to human activities

Arctic and alpine ecosystems are particularly vulnerable to human impacts on species diversity, because there are few species in the most widespread vegetation types, so the loss or gain of even one or two species has a large proportional impact on diversity. Furthermore, landscape diversity is easily altered by human impact, due to the sensitivity to disturbance of steep alpine slopes and the sensitivity of Arctic soils to permafrost degradation. Resulting ecosystem changes affect local inhabitants primarily by reducing the productivity of various animal species (reindeer, marine mammals, fish) on which they depend. In alpine and down-slope ecosystems, these changes influence run-off, landslide danger and the quality of drinking water. Other effects of human-induced changes on Arctic and alpine ecosystems are indirect, resulting from potential positive

feedbacks of CO₂ and CH₄ emissions to climate warming. Because human impacts on the Arctic and alpine regions originate primarily outside these regions, they are generally decoupled from, and unresponsive to, the effects they cause.

6.1.2 Tropical forests

6.1.2.1 Introduction

Tropical forests grow in frost-free regions between the Tropic of Cancer and the Tropic of Capricorn. In the New World, evergreen forests of the humid tropics extend from the border of the San Luis Potosí–Veracruz States of Mexico (Dirzo and Miranda 1991a), south to the east coast of Brazil. In Africa, these forests are confined to the Guinea coast, the Zaire Basin and the eastern part of Madagascar. In Asia, they are found in the monsoon areas north to the southern slopes of the Himalayas, in southeastern India, and in Malaysia, Indonesia, the Philippines, Thailand, and New Guinea. Evergreen tropical forests extend south in a narrow discontinuous strip on the east coast of Australia.

Most tropical forest regions, even the wettest ones, have dry seasons during which one to several months may receive <100 mm of rain. Only in Malaysia and Indonesia are there large areas that are always wet (i.e. >100 mm of rainfall per month) (Walter 1973). Tropical areas with longer dry seasons are typically found poleward from wet forest regions, but they also exist in regions that are dry for topographic reasons. If these areas have not been heavily disturbed, they support moist and dry deciduous forests. In tropical and subtropical regions with lengthy dry seasons, rainfall reaches its maximum at the time the sun is at its zenith; the winter months, which are only slightly cooler than the summer months, are relatively dry.

Rainfall increases with elevation on the slopes of tropical mountains except in areas that lie in the lee of tall mountains. Clouds form on most days around 1500 metres above sea level, with the result that cloud forests prevail between 1000 and 2500 m on mountain slopes. Precipitation decreases rapidly above the cloud belt. Forests above the cloud zone have short stature and the leaves of trees are smaller and more xeromorphic than those at lower elevations. Above these low-stature forests is a zone dominated by scleromorphic shrubs (Grubb 1977).

One of the most distinctive features of tropical forests is their biological richness, particularly in numbers of species. The world records for species richness are 473 tree species (considering only individuals with a diameter at breast height (dbh) of 10 cm or more) in a 1 hectare plot in Amazonian Ecuador (Valencia *et al.* 1994), which supersedes the previously known and highly publicized record of 300 woody species (trees and lianas dbh >10 cm) in a 1 ha plot in Ecuador (Gentry 1988) (see also Section 3.2 and Latham and Ricklefs (1993) for an analysis of tree species diversity) and 1200 species of beetle collected from a single tree species in Panama (Erwin 1982). Fourteen of the 18 areas on Earth with unusually high degrees of plant endemism lie within the moist tropics. Their collective expanse, which is smaller than California, constitutes less than 5% of the remaining undisturbed forests. These forests contain more than 37 000 endemic plant species, or 15% of all plant species, in less than 311 000 km², or just 0.2% of the Earth's land surface (Myers 1988, 1990). Plant life-forms are also exceedingly diverse in tropical forests and include trees, shrubs, herbs, epiphytes, hemi-epiphytic trees, epiphytic cacti, terrestrial and climbing palms, climbing herbs, bamboos and more (Richards 1952; Whitmore 1975; Gentry 1990). These impressive figures of tropical biodiversity should not conceal the fact that our current knowledge is still very limited. Two splendid accounts of our ignorance on this subject are those of Gentry (1992) for plants and Gaston (1991) for insects. The following statements taken from these two sources provide compelling examples. In the supposedly well-collected region of Iquitos, Peru, nearly 70% of extracted timber comes from a tree first described in 1976, and the most common climbing species in the inundated forests of this area was first discovered in 1976. For insects, estimates of the proportion of tropical species still not described range from a low of perhaps 65%, to a high of 99% (see Section 3.1.2).

For unknown reasons, these forests are relatively resistant to invasions; invaders tend to be restricted to disturbed rather than natural areas (Rejmanek 1989; Whitmore 1991).

6.1.2.2 Human impacts on biodiversity

Considerable attention has been directed towards tropical forests because their rate of loss is currently very high (Myers 1989; Lanly *et al.* 1991; Whitmore and Sayer

1992). According to the last published calculations of FAO (1990), tropical closed forests were being destroyed at a rate of at least 110.5 million ha per year. Rates of loss of forest cover vary greatly by continent and habitat type, and true deforestation rates are difficult to determine because satellite data are incomplete and ground truthing is available for relatively few areas (Myers 1994). In Central America, more than 95% of tropical dry forest has been converted to agriculture, whereas a much higher percentage of evergreen humid forest still remains (Janzen 1988). If recent rates of destruction of tropical forests continue, massive extinctions of populations and species are expected to occur in the coming years and decades (Wilson 1992; Whitmore and Sayer 1992).

The extensive conversion of forests to pastures and agricultural lands as well as shifting cultivation and forestry plantations in Southeast Asia greatly reduce biodiversity at both local and landscape scales. Few of the many species that make tropical forests the richest habitat type on Earth can survive in the croplands, pastures or second-growth forests that replace the forests. However, some of them can be extremely successful in those habitats (e.g. *Cecropia* spp. and *Ochroma pyramidale*, among other plants (Gómez-Pompa and Kaus 1992). In addition, because of their narrow ranges many tropical species are vulnerable to extinction from loss of forests in local areas. For example, many species of cloud forest plants in tropical Latin America are endemic to isolated sites smaller than 10 km² (Gentry 1992) while among the birds of tropical forests in South America, 440 species (25% of the total) have ranges of less than 50 000 km². In contrast, only eight species (2% of the total) of bird species in the United States and Canada have such restricted ranges (Terborgh and Winter 1980).

6.1.2.3 Productive capacity, biomass, decomposition and nutrient cycling

Primary productivity of tropical forests is apparently positively correlated with plant species richness only when the number of species is far below that which characterizes most mainland tropical forests, even those that are fragmented and highly disturbed (Vitousek and Hooper 1993; Wright in press). However, some tropical forests, especially those growing on unusual soils, are dominated by one or a few species of trees (Connell and Lowman 1989; Hart 1990). Examples include *Mora excelsa* stands adjacent to mangrove forests (Richards 1952); *Eperua* forests in South America (Richards 1952; Klinge and Medina 1978; Klinge and Herrera 1983; Herrera *et al.* 1984; Cuevas and Medina 1988), and the *Pterocarpus officinalis* or *Celaenodendron mexicanum* forests of Mexico (Martijena 1993). These forests have not been studied well enough to determine whether their productive capacity is influenced by their low species richness. Recent

studies have failed to detect significant differences in nutrient levels of soils between forests dominated by *Celaenodendron mexicanum* and adjacent mixed (diverse) patches of seasonally dry forests (Martijena 1993) or between evergreen forests dominated by single species and mixed forests in India (Kadambi 1942), Zaire (Hart *et al.* 1989; Hart 1990) and Malaysia (Whitmore 1975).

None the less, biodiversity may influence tropical forest productivity if there is much variation in weather and if disturbances are relatively frequent or severe. Annual productivity is higher and less variable in species-rich than in species-poor temperate grasslands because some species perform better during wet years, while others do better during dry years (Tilman and Downing 1994). It is possible that a similar variation in performance occurs among tropical trees, but we are unaware of any relevant data. Gathering such data may be difficult because little variation is expected in the number of leaves produced per unit area. The rate of biomass accumulation depends strongly on the nature and intensity of disturbance, and species differ in the speed with which they respond to disturbances. Therefore, although there are no data available to test the hypothesis, species richness may influence the rate at which biomass accumulates after disturbance (Denslow 1995).

The consequences of forest disturbance for ecosystem productivity and nutrient cycling depend on the scale and frequency of the disturbance. In the Atlantic lowlands of Costa Rica, intermediate-scale experimental clear-cutting of forests on residual soils resulted in rapid, short-term increases in nutrient concentrations in soil solutions, increased percolation of water through the soil, and increased losses of soil nutrients (Parker 1994). With no additional disturbance, the large pulse of nutrients lost below the rooting zone in percolating water was transient: concentrations returned to pre-disturbance levels in less than two years. Small-scale disturbances, such as in natural or artificial treefall gaps, do not result in increased soil nutrient availability (Vitousek and Denslow 1986) or solution losses (Parker 1994) compared to the intact forest. On the other hand, large-scale, long-term conversion of forests to grasslands or cropland results in major changes in nutrient pools and the soil biota (Olson 1963; Hamilton and King 1983; Macedo and Anderson 1993; Henrot and Robertson 1994). In combination with extraction of nutrients in harvested biomass, these changes cause the productivity of the transformed tropical agro-ecosystems to decrease rapidly.

Litter decomposes so rapidly on the floor of lowland tropical wet forests that there is no interannual accumulation of decomposing litter (Barrow 1991). Hence, tropical trees may not influence the development of soil profiles in highly species-specific ways as strongly as they do in high-latitude forests. However, tropical trees differ markedly in tissue chemistry (Rodin and Basilevich 1967;

Golley 1983a, b), suggesting that they differ in what they remove from the soil and what they deposit on the soil surface. Soils under the legume *Pentaclethra macroloba* at La Selva, Costa Rica, have lower pH values than soils away from individuals of this species, presumably because the trees fix nitrogen, which is then nitrified (Parker 1994). Soils under female *Trophis involucrata* individuals have higher phosphorus concentrations than soils under males (Cox 1981). The meager evidence so far available suggests that trees of different species may generate significant differences in the soils in the areas affected by their roots and litter fall, but whether these differences are important for regeneration, growth, species richness and productivity of tropical forests remains to be determined (Parker 1994).

6.1.2.4 Water distribution, balance and quality

Deforestation, agricultural practices and soil erosion reduce landscape complexity and diversity and also result in the pollution of many rivers and streams that flow through tropical forests. Pollution can alter species diversity and trophic dynamics considerably, as in the case of lead- and mercury-polluted segments of the Orinoco River caused by gold mining (Pfeiffer and De Lacerda 1988).

Alteration of landscape structure and diversity affect water distribution and balance in terms of the seasonal variation in runoff to rivers and lakes and associated nutrient inputs. Water distribution and quality are also affected by the type of management techniques and the diversity components associated with management practices. For example, in a seasonally dry forest in Mexico, soil erosion within the forest was negligible (< 2 Mg/ha/yr), whereas conversion to maize and grassland increased erosional losses up to 130 Mg/ha/yr (Maass *et al.* 1988). In this study, as much as 185 k/ha of nitrogen, 27 k/ha of phosphorus, and 378 k/ha of calcium were lost via erosion within a year of deforestation, whereas less than 0.1 k/ha of each element was lost from the intact forest. Presumably, the nutrients eroded from deforested soils end up in neighbouring rivers and lakes where they alter water quality. In addition, runoff from cut-over forests leads to erosion along tropical coasts, which may cause death to corals.

6.1.2.5 Atmospheric properties and feedback

Tropical deforestation and subsequent conversion to other simplified systems (largely grasslands) lead to changes in the rates of fixation and storage of carbon in vegetation. Tropical forest destruction and burning is currently a net source of atmospheric CO₂, but this is due to reduction of the total acreage of forests and to extensive burning (Detwiler and Hall 1988; Hall and Uhlig 1991; Houghton 1991) and not to loss of species *per se*. In general, tropical wet forest deforestation contributes more to carbon emissions than does cutting of seasonally dry forests

(Masera *et al.* 1992). Conversion to grassland, the most common type of forest conversion in the tropics, contributes the largest amounts of carbon emissions (Masera *et al.* 1992). Because tropical plantations can and do accumulate carbon at rates similar to those of natural species-rich forests (Cuevas *et al.* 1991; Ewel *et al.* 1991; Lugo 1992), there is no reason to expect that carbon budgets of tropical forests are strongly influenced by species richness.

Tropical wetland areas are a major global source of methane, but upland tropical soils can be significant methane sinks. Conversion of upland tropical forests to agriculture can transform these soils from methane sinks to net methane sources. Agricultural activities and development projects that alter, destroy or create (artificial) tropical wetlands also affect biodiversity components of these systems with potential atmospheric effects. Methanogenic bacteria in tropical wetlands are responsible for 60% of the total global methane emissions from natural sources, but gut symbionts of termites are also a significant source of methane (Wassmann *et al.* 1992; but see Martius *et al.* 1993). How emission rates of methane and other chemicals vary with biodiversity is unknown, though ongoing research indicates that emission rates vary with the species of termite.

6.1.2.6 Landscape and waterscape structure

Deforestation is dramatically altering tropical forest landscapes and waterscapes (Shukla *et al.* 1990). However, although deforestation is causing reductions in species diversity, there is no evidence that species loss is, in turn, influencing the structure of landscapes or waterscapes. It has been established that, in Amazonia, tropical landscape modification in the form of transformation of forest to grassland may alter local climate, particularly through the intensification of rainfall seasonality (Shukla *et al.* 1990).

6.1.2.7 Biotic linkages and species interactions

Deforestation, fragmentation and isolation, edge effects, contemporary defaunation (*sensu* Dirzo and Miranda 1991a), and reduction of forest habitat size (Lovejoy *et al.* 1986) have profound effects on biotic linkages and species interactions. Most tropical plants are animal-pollinated (Bawa 1979; Bawa and Beach 1981; Baker *et al.* 1983; Bawa and Hadley 1990); they are fed upon by a wide variety of generalist and specialist herbivores (Dirzo 1987); and they also depend upon animals for dispersal of their seeds (see Estrada and Fleming 1986). Flowering plant species inhabiting forest fragments can experience severely reduced rates of pollinator visitation which can lead to reduced seed production and/or genetic diversity of progeny (Aizen and Feinsinger 1994a, b). Similar effects may be operating as a consequence of reductions in the abundance of critical pollinators, such as Euglossine bees

in Amazonian forest fragments (Lovejoy *et al.* 1986), or the outright loss of hummingbird species on Panama's Barro Colorado Island (Karr 1982). Reduction or loss of other species or functional guilds as a consequence of forest fragmentation (e.g. seed-dispersing birds and bats) may also affect plant reproductive biology, forest structure and forest dynamics. Fragmentation and isolation also alters the guild of vertebrate seed consumers in fragmented tropical landscapes, thereby affecting floristic composition (Cox *et al.* 1991; Dirzo and Miranda 1991a; Leigh *et al.* 1993). Contemporary defaunation (due to habitat alteration and hunting) of medium- to large-sized understorey vertebrates is correlated with local reductions of floristic diversity and the occurrence of monospecific seedling carpets in tropical forests (Dirzo and Miranda 1991b). Although the long-term ecosystem consequences of such changes have not been studied, biodiversity disruptions such as defaunation and creation of local monocultures probably affect patterns of litterfall deposition and possibly nutrient dynamics. Long-term ecosystem consequences of alterations of biotic diversity in the tropics warrant further study.

Secondary productivity is potentially highly sensitive to species richness because different plants allocate their primary production in highly distinctive ways. Plant species differ strikingly in the proportion of primary production allocated to defences; which defensive compounds are synthesized; the quantities and composition of tissues that function to attract mutualists (Coley *et al.* 1985; Davidson *et al.* 1991) and the chemical composition of their wood. Because tropical climatic conditions allow heavy herbivore pressure throughout the year, tropical woody plants allocate relatively large amounts of energy to the production of chemical defences (Levin 1978; Levin and York 1978; McKey 1979) and to the production of resources that attract predators and parasites of herbivores (Simms 1992). Consumers may increase primary productivity by maintaining individual plants and plant populations in rapid growth phases, by reducing the accumulation of living plant biomass, by reducing respiratory losses, and by recycling nutrients, but the relatively small amount of new primary production typically consumed by herbivores in tropical forests probably has little effect on total net primary production (Huston 1994).

'Mobile link' species (i.e. animals necessary for the persistence of plant species that in turn support otherwise separate food webs – Gilbert 1980, pp. 19–20), such as pollinators, seed dispersal agents and plant defence mutualists, alter fluxes of energy and materials very little in ecological time, but they may be critical to the maintenance of the species richness of tropical forests. Many species in tropical forests depend upon a small suite of frugivores for dispersing their seeds. Loss of these species, many of which disappear when forests are fragmented, may

adversely affect the long-term population viability of many tree species (Howe and Smallwood 1982; Terborgh 1986).

6.1.2.8 Microbial activities

Fungi and bacteria are involved in a wide range of fundamental processes in tropical ecosystems, from global geochemistry to decomposition and nutrient cycling (Hawksworth *et al.* 1996). However, the taxonomy of tropical microbes is so poorly understood that we know very little about the functional roles played by individual taxa and how sensitive ecosystem processes are to human-induced deletions of these species. Although we know very little about the effects of tropical deforestation on microbial biodiversity, it is clear that microbial activity declines considerably in cleared areas. One possible way in which microbial activity may be affected is by differential effects of human activities on plant species that associate with nitrogen-fixing bacteria, but there is no evidence of such effects in tropical forests. However, we speculate that in forests remaining near deforested areas the edge effect, which is known to increase tree falls and forest turnover rates, may indirectly affect microbial diversity through the creation of advancing fronts of secondary plant species, with leaf chemistry and litterfall characteristics different from those of the mature forest. Deforestation and fragmentation which threaten the entire guild of nitrogen-fixing microbes may directly affect productivity and nutrient cycling in tropical forests.

In mature forest patches, in comparison to gaps, plants grow slowly, use nutrients efficiently, and produce relatively low-quality litter that decomposes slowly and may deter litter herbivores. Gap pioneer species, in contrast, grow rapidly, produce comparatively more degradable litter, and are easier to use by litter feeders — thus enhancing rates of nutrient cycling (Hobbie 1992). In addition, positive feedbacks to nutrient cycling may arise due to species differences in carbon deposition and competition with microbes for nutrients in the rhizosphere.

6.1.2.9 Summary and relevance to human activities

Humans are impacting biodiversity in tropical systems primarily through forest destruction, largely for conversion to pastures, cropland and plantations. Current rates of habitat loss and associated species loss are higher in tropical regions than elsewhere in the world (Janzen 1988; Raven 1988; Whitmore and Sayer 1992). Reductions of intraspecific genetic diversity are poorly documented, but they are certainly taking place, perhaps at a very serious level. Other human activities that affect biodiversity and ecosystem functioning include water pollution and development projects such as dams, but the ecosystem consequences of such perturbations are poorly known. It is sometimes assumed that the profusion of species in tropical forests may compensate for the loss of some or many of

them. However, given the paucity of data on many critical aspects of the relationships between biodiversity and ecosystem processes, such an assumption is unwarranted and may be dangerous.

North and South America and on the islands of New Zealand and Tasmania. In Western Europe and in the eastern part of the United States and Canada, precipitation is equitably distributed as snow or rain throughout the year. In eastern Asia, under a monsoon climate, most of the precipitation falls in the summer. Along the Pacific coasts of North and South America, where the climate is more Mediterranean, precipitation occurs mainly during the winter months. The forests are dominated by deciduous and, to a lesser extent, evergreen broad-leaf and needle-leaf trees encompassing a potential area of about 18.6×10^6 km² (Melillo *et al.* 1993), more than 50% of which has been converted to cultivation (Matthews 1983). In total, more than 1200 tree species are represented. Differences in history since the Tertiary have caused large variations in tree diversity in the four regions. East Asia, in spite of extensive reduction in forest area, has six times as many species as North America, eight times more than Europe, and eighteen times more than Chile.

6.1.3.2 Productive capacity, biomass, decomposition and nutrient cycling

Human impacts on biodiversity. For centuries the temperate forest regions have experienced intensive human activity. The East Asian forests of China were the first to be largely cleared for agricultural development before 3200 BP (Teng 1927). Clearing followed much later in Europe, North America and much of the Southern Hemisphere (Perlin 1989). In addition, many native forests have been converted to plantations of a few species, largely represented by conifers. Human activities have affected biodiversity in forests to a lesser extent by introducing pests and pathogens, by creating air and water pollution, and by selectively harvesting various products (tree species, game animals, mushrooms and litter). If, through consumption of fossil fuels, humans induce predicted climatic change, the biodiversity of temperate forests as well as other biomes will be substantially altered (Peters and Lovejoy 1992).

Ecosystem consequences of impacts. A major consequence of clearing activities is a reduction in ecosystem carbon stores, in both biomass and soil organic matter. Globally, temperate forests today, although much smaller in extent than originally, are thought to be a net sink for carbon dioxide exchange (Tans *et al.* 1990). If so, this is mainly the result of faster growth rates associated with younger forests (Wofsy *et al.* 1993). The total biomass, both alive and in dead woody material, is much less in young forests than in older ones (Waring and Franklin 1979). Although biodiversity in plantations is usually reduced, growth rates are generally increased due to genetic selection and intensive management. Air and water pollution, pest and pathogens, and most harvesting practices tend to increase the rates at which minerals cycle

6.1.3 Temperate forest systems

6.1.3.1 Introduction

Temperate forest ecosystems of the mid latitudes occupy a climatic zone with pronounced variation in seasonal temperatures. Distribution is mainly in the Northern Hemisphere, in Europe, East Asia and eastern North America. In addition, representatives of this biome exist in a narrow band of rain forest along the Pacific coasts of

and nutrients are lost from the forest ecosystem. Genetic and species diversity is usually sufficient, however, for maintenance of net primary production, given time for re-establishment of a full canopy (Shugart and West 1977). Immediately following forest clearing the microbial system is able to sequester critical nutrients and prevent their loss by leaching (Vitousek and Matson 1985; Griffiths *et al.* 1994).

6.1.3.3 Soil structure and nutrient pools

Human impacts on biodiversity. Frequent disturbances associated with thinning and harvesting activities modify the surface litter and may compact the soil, which causes surface runoff and erosion from steep ground. The increasing use of fertilizers in forestry and agriculture, combined with nitrogen and sulphur in the atmosphere derived from consumption of fossil fuels, add to wet and dry deposition of these elements (Galloway *et al.* 1987). Unpaved roads create dust, and winds distribute calcium, potassium and other elements across wide areas (Hedin *et al.* 1994). Where ozone levels are high, and combine with atmospheric deposition of heavy metals, the recycling of nutrients through decomposition may be slowed, and may eventually limit the production of organic matter (Tyler 1972). Pests and pathogens, on the other hand, have fewer long-term effects and generally increase the rate at which minerals and nutrients cycle through soils (Waring and Schlesinger 1985).

Ecosystem consequences of impacts. The practice of clear-felling all the trees in a watershed temporarily increases the export of nutrients into groundwater, lakes and streams (Likens *et al.* 1978). Unless land is permanently cleared, however, the soil organic matter content is not substantially reduced (Gholz and Fisher 1982). The microbial system associated with shrubs and other vegetation may survive on dead roots and is usually sufficient to prevent immediate mobilization of critical nutrients (Vitousek and Matson 1985). In much of the temperate forest region, where forests are rarely clear-felled, wet and dryfall from air pollution acidifies soils and increases N and S pools. As a result, leaching of cations (Ca, Mg, K) is accelerated and seepage water is enriched in nitrogen (Schulze 1989). Even without atmospheric deposition, monocultures of evergreen species may acidify soils (Last and Watling 1991), although this depends on the type of soil, the species of evergreens (Speirs *et al.* 1986), and the presence of species that may cycle calcium or other elements from deeper soil horizons (Thomas 1959; Attiwell and Adam 1993).

6.1.3.4 Water distribution, balance and quality

Human impacts on biodiversity. Fragmentation of forests causes increased desiccation of canopies into the interior of remaining forests (Saunders *et al.* 1991; Chen *et al.* 1995).

As a result, epiphyte cover is reduced and less precipitation is intercepted by the canopy. Outbreaks of insect defoliators occur more regularly, causing a weakening of the surviving trees which reduces their flower and seed production, which in turn limits the number of vertebrates and invertebrates present. Replacement of deciduous forests with extensive plantations of evergreens increases stream-flow (Swift *et al.* 1975). A closed forest canopy along stream channels prevents the development of an algae-based food chain in the aquatic system (Triska *et al.* 1982). Where forests are frequently cut or where agricultural lands are intermixed with forests, surface and subsoil runoff to streams increases. The runoff carries with it soil, minerals, and often pesticide residues that degrade the stream habitat and reduce species diversity. As a result, spawning habitat for salmon, striped bass and other commercial and sport fisheries has been lost throughout much of the temperate forest region, and surviving populations of fish and other aquatic animals often carry high residues of pesticides.

Ecosystem consequences of impacts. Reduction in the leaf area of forests, and conversion to agricultural or urban development, greatly impact the way in which solar energy is dissipated. At full leaf area, a forest may transpire the equivalent of 3–5 mm water per day. Agricultural crops do not develop a full canopy until mid growing season and are harvested before the end of the normal growing season so that the total surface of foliage available for interception and evaporation is much reduced compared to forested conditions. Urban landscapes transpire or evaporate even less water. Peak storm flow increases following forest disturbance, causing flood damage downstream (Waring and Schlesinger 1985). The shorter stature of vegetation in fields and woodlands that replaces mature forests tends to make the surrounding area warmer (Kelliher *et al.* 1993). A major impact of forest removal is upon streams. Loss of shade increases water temperatures, and harvesting activities reduce the periodic addition to streams of large woody debris that creates pools and enhances the processing of dissolved and particulate organic matter. Increased erosion fills channels and allows silt to accumulate over gravels in which spawning fish lay their eggs. Acidification and pesticide residues further limit the ability of stream organisms to process organic matter and to remove harmful materials.

6.1.3.5 Feedbacks to atmospheric properties

Human impacts on biodiversity. Fragmented landscapes composed of deciduous woodlands, evergreen forests, fields and urban areas, absorb solar radiation differently from a uniform cover of vegetation. With generally less surface area in forest canopy, evaporative cooling is reduced and the meso-scale climate becomes less stable (Pielke *et al.* 1991). Dust and haze created by air pollutants

reduce incident solar radiation. Conversion to plantations of conifers increases the production of hydrocarbons by the vegetation (Chameides *et al.* 1988).

Ecosystem consequences of impacts. The presence of forest cover increases the surface area of exchange for the deposition of aerosols by up to 20 times that of bare ground while the loss of the forest canopy and its epiphyte community allows wider distribution of the aerosol load (Lindberg *et al.* 1986). Haze generated by compounds produced by trees or by human activities diffuses light and increases the efficiency of photosynthesis by plants. The concomitant reduction in solar radiation heats surfaces less and reduces respiration so that net ecosystem carbon balances may not be changed as much as otherwise predicted (Hollinger *et al.* 1994). Evergreen forests reflect less solar energy than deciduous forests (Goward *et al.* 1994). As a result, when separate blocks of deciduous and evergreen forests are present, heat islands develop, which increase afternoon thunderstorm activity (Nicholls *et al.* 1995). Snow that accumulates under evergreen forests will not reflect as much solar radiation as that deposited under deciduous canopies. The presence of snow may also lengthen the start of the growing season by delaying soil warming.

6.1.3.6 Landscape and waterscape structure

Human impacts on biodiversity. Agriculture, urbanization, road building and surface mining throughout temperate forest ecosystems have substantially altered landscape structure and diversity. The building of roads introduces corridors for the transportation of plants, insects and pathogens. Road construction also increases hillslope erosion, which reduces landscape diversity. The removal of forests along the floodplains reduces the capacity of the land to store water, which leads to more rapid runoff and excessive flooding when dam capacities are exceeded. The simplification and instability of floodplain vegetation are increased when unstable slopes are present in upper drainages. In total, the overall diversity of habitats is reduced across a drainage area when forests are fragmented or converted to other uses.

Ecosystem consequences of impacts. The net effect of reduced forest cover is accelerated transfer of soil, organic matter and water into streams, lakes and reservoirs, and because water carries high concentrations of nutrients, eutrophication of waterways results. The general effect is degradation and simplification of aquatic systems. Pollution, and the introduction of nonnative plants, insects and pathogens, make native forests less resilient and thus more sensitive to periodic disturbance and sustained nutrient losses. As a result, the productive capacity of the landscape may be degraded, and in extreme cases prevented from supporting forests (Schulze and Ulrich 1991).

6.1.3.7 Biotic linkages and species interactions

Human impacts on biodiversity. With increased commerce between continents, many insects and pathogens have been introduced into forests without co-evolved biotic controls. For example, virulent pathogens such as Dutch elm disease (*Graphium ulmi*) and chestnut blight (*Endothia parasitica*) have largely removed their respective host trees from the landscape in the eastern US. Gypsy moth (*Lymantria dispar*) and other introduced insects have also caused extensive damage. In addition, invasive plants such as Kudzu (*Pueraria lobata*), a nitrogen-fixing vine, have taken over many areas in the Southeastern USA and restricted the regeneration of forests. When European livestock were introduced into the New Zealand forests they destroyed much of the native vegetation, which was ill-adapted to browsing, and caused excessive compaction of the soil (Veblen and Stewart 1982). Air pollution has greatly reduced the epiphytic component of forest canopies (Hawksworth and Rose 1970) as has the conversion of old-growth forests to younger age classes (Sollins *et al.* 1980). More locally, where road systems are well developed, organisms are readily transported across natural boundaries, often without their biotic controlling agents. Pesticide applications to farmland and forests accumulate in food chains and are particularly harmful to raptors (Carson 1962), and reduction in forest cover, combined with bounty hunting and trapping, has caused the extinction of many large carnivores such as wolves, bears and mountain lions. Keystone species such as beaver and coypu have also been lost. Selective management of forests for particular sizes and types of trees has great consequence for the diversity of all species, as do policies for fire suppression, waste deposition and air pollution. The reduction in the area of forests, together with loss of tree species, has an especially hard impact on bird populations. Birds that migrate between temperate and tropical forests are most affected because they are losing habitat in both biomes (Wilcove 1990). Reduction in bird populations allows defoliating insects to reach epidemic population levels more frequently and thus further endangers the survival of some species of trees (Crawford and Jennings 1989; Mason *et al.* 1983).

Ecosystem consequences of impacts. Continual reduction in forest cover accentuates pollution, erosion and species extinction. Forests managed on short rotations limit diversity: fire protection, on the other hand, may lead to equally unstable conditions where multiple age classes of trees provide excessive accumulation of fuel. Thinning and salvage logging have an important role to play in such situations. Management may also ameliorate the effects of acid rain by liming soils and surface waters and by judicious tree harvesting, careful road construction, and expansion of land conservation policies. Some opportunities for organic matter recycling from urban areas

and agricultural fields into forests may buffer trends, but heavy metal concentrations and excessive applications of fertilizer lead to more polluted streams and ground water. Policies that favour fire protection often result in a change in species composition and a more fire-prone situation than normal. On the other hand, short cutting cycles or selective harvesting of the largest trees reduces habitat niches for many species of vertebrates and invertebrates while increasing the availability of forage for a few species of ungulates (Turner *et al.* 1994). Birds, butterflies and other species that migrate between temperate and tropical forests are particularly sensitive because losses of habitat are occurring in both types of forests. The loss of keystone animals such as beaver and coypu from most of the temperate forests has reduced the area of wetlands and the availability of habitat for fish, birds and other animals. Loss of large carnivores allows populations of ungulates to oscillate more widely, resulting in selective removal of more palatable deciduous shrubs and trees unless hunting pressures are increased accordingly. If headwater forests, floodplain woods and adjacent wetlands can be protected in corridors, some buffering may be provided against erosion and the eutrophication of water bodies, even with expanded use of other lands.

6.1.3.8 Microbial activities

Human impacts on biodiversity. Most temperate forest ecosystems have a large capacity to store nitrogen, but chronic additions may lead to saturation (Aber *et al.* 1994). Deposition of heavy metals in sewage sludge or from atmospheric sources represents an increasing problem near urban areas. Increases in the evergreen component of forests changes the quality of litter for microbial activity, while removal of the litter for bedding, as was done in Europe for centuries, leads to impoverished substrates. Atmospheric additions of S and N encourage microbial activity that converts these elements to gases. At the same time, other functional groups of microbes may be lost, such as N-fixing bacteria and many fungi adapted to low levels of nutrients.

Ecosystem consequences of impacts. Increased enrichment with nitrogen and sulphur may not enhance microbial decomposition if the carbon substrate is inappropriate, particularly if symbiotic fungi (mycorrhizae) become less active on the roots of trees and other plants. On the other hand, denitrification and trace gas production of sulphur compounds is enhanced (Aber *et al.* 1994) unless heavy metal concentrations are sufficient to limit microbial activity. Loss of earthworms due to compaction and acidification reduces mixing and will further limit decomposition rates. Global increases in atmospheric CO₂, however, may result in more carbon being allocated by plants to mycorrhizal fungi, which should enhance nutrient mobilization in the rooting zone. Concomitant changes in

climate may completely alter forest composition and distribution (Neilson and Marks 1994).

6.1.3.9 Summary and relevance to human activities

The dominant effect of human activity on temperate forest ecosystems has been their conversion to agricultural use. Large plantations of single species of conifers and hardwoods, combined with more frequent harvesting, exert a major impact on ecosystem functioning and biodiversity. In the last half-century, air pollution has changed the properties of the atmosphere and precipitation, and this has resulted in the removal of some species, alterations in nutrient cycling, and the creation of ecosystems more susceptible to outbreaks of insects and diseases. Loss of some keystone species and the introduction of others further destabilize temperate forest ecosystems. The full impact of changes in the chemical composition of the atmosphere induced by human activity is not known but if climatic conditions change rapidly, as they are predicted to do, we would expect forests composed of long-lived trees, typically with infrequent seed production, to be particularly vulnerable, along with the complex food chains they support. As a result, we predict largely negative consequences on biodiversity, net primary production, and net ecosystem production with rapid climate change.

6.1.4 Arid and semi-arid lands

6.1.4.1 Introduction

In arid lands, water availability (precipitation vs. evaporative demand) imposes severe constraints on biological activity. Precipitation is characterized by unpredictability in time and space as well as by low total amounts (Noy-Meir 1973). Semi-arid ecosystems differ from true arid areas in structure and in the rate and regulation of ecosystem processes. We differentiate between these two, and highlight cases of conversion from semi-arid to arid lands (desertification; Verstraete and

Schwartz 1991). Biodiversity, reflected in species richness, is moderately high in semi-arid regions and declines with increasing aridity for most taxa (Shmida 1985; Pianka and Schall 1981; O'Brien 1993). Certain taxa are diverse relative to other biomes (e.g. predatory arthropods, ants and termites, grasshoppers, snakes and lizards, rodents, annual plants), but there is substantial variation in the richness of particular taxa among the deserts of different continental areas. The abundance and activity of desert organisms are 'pulsed' in correspondence with episodes of high moisture availability (Noy-Meir 1973; Louw and Seely 1982); while the prevalence of dormancy, cryptobiosis, aestivation and other modes of escaping harsh conditions means that most of the biodiversity of arid regions can be impossible to census or sample during most time periods.

6.1.4.2 *Productive capacity, biomass, decomposition and nutrient cycling*

Human impacts on biodiversity. Human activity has caused changes in the biodiversity of arid lands primarily through the use of arid and semi-arid systems for grazing of livestock. Introductions of domestic and game animals have altered the character and the magnitude of animal consumption (Oosterheld *et al.* 1992), and these have been accompanied by creation of water points, introduction of non-native plants, and removal of predators and of burrowing and herbivorous animals seen as threats to livestock. Plant species diversity decreases when the local extinction of grazing- or trampling-sensitive species exceeds the establishment of new grazing-tolerant or weedy species (Westoby *et al.* 1989; Milchunas and Lauenroth 1993); after a time lag, loss of native plant species may result in a loss of animal taxa (Jones 1981; Jepson-Innes and Bock 1989; Heske and Campbell 1991). In some regions the intensive cultivation of irrigated croplands has eliminated large portions of native ecosystems (Jackson *et al.* 1991).

Ecosystem consequences of impacts. In North America and Africa, semi-arid grasslands have often been converted to shrublands by grazing and by the dispersal of shrub seeds by livestock (e.g. Peinetti *et al.* 1993), leading to a different structure and display of biomass as well as altered species composition (Schlesinger *et al.* 1990). Production will be reduced if grazers remove leaf area and cause an increase in the proportion of water lost to evaporation, rather than being used by plants. However, net primary productivity or NPP (the amount of plant material produced by photosynthesis per unit area over a time period) is not necessarily changed by changes in plant species composition induced by grazing (Milchunas and Lauenroth 1993). Decreases in NPP are most pronounced where there has been no long evolutionary history of intense grazing (Milchunas and Lauenroth 1993). Some semi-arid and arid ecosystems comprise diverse assemblages of different plant

growth forms, physiologies and life histories, which form distinct guilds with respect to water use because of correlations among morphological, phenological and physiological traits (e.g. Golluscio and Sala 1993). Where the members of a guild (e.g. perennial grasses using shallow water during the hot season) respond similarly to a disturbance (e.g. are all grazing-sensitive), the elimination of that functional group will have direct influences on the structure and functioning of the ecosystem. In addition, the importance of macro-organisms in determining microbial populations (Gallardo and Schlesinger 1992) means that removal of plants or alteration of the distribution and abundance of plant roots will alter the pool and rates of activity of decomposers, thus altering rates of decomposition as well as of organic matter inputs. Termites and nest- or burrow-building mammals provide micro-environments that enhance decomposition and nutrient cycling. Their removal by humans has the potential to slow decomposition and increase the chances of loss or transport of nutrients from the surface (Whitford 1991).

Conversion of semi-arid or arid lands to agriculture (usually by irrigation) may increase local NPP values, but the effects on biodiversity are severe. Native plant communities are displaced, and are notoriously difficult to restore after cessation of cultivation (Jackson *et al.* 1991). In India the birds of semi-arid regions have proved especially likely to disappear following cultivation and fragmentation of native habitats (Daniels *et al.* 1990). It is not clear how human activities have altered the role that fire plays in semi-arid regions. In some places fires may have maintained semi-desert grassland, suggesting that grazing (causing the reduction of fuel loads) and fire suppression have contributed to the conversion of grasslands to shrublands. However, in other systems the perennial grasses appear to be more sensitive to fire than the woody plants (Wright 1980), and there is no clear guideline for the use of fire in maintaining grassland or manipulating species composition (Bock and Bock 1992).

6.1.4.3 *Soil structure and nutrient pools*

Human impacts on biodiversity. Introduction of hoofed livestock to regions lacking a recent evolutionary history of ungulate grazing (e.g. Australia, southwestern North America) has been the primary human effect on the biodiversity of semi-arid regions. This has been accompanied by reduction of populations of native burrowing herbivores (e.g. North American prairie dogs, Australian marsupials), thus reducing the soil-disturbing activities of these animals.

Ecosystem consequences of impacts. The introduction of large hoofed animals to regions previously lacking them has caused changes in the compaction of soil, reducing infiltration (Roundy *et al.* 1992), while also churning up dry surface soil and increasing its vulnerability to erosion.

Vegetation influences the 'roughness' of the surface, which in turn influences the movement and erosive power of wind and water (e.g. Abrahams *et al.* 1994); thus the activities of livestock (or humans) have direct influences on the rates of erosion of surface layers. Erosion and transport of surface soil particles will in turn influence the transport and loss of mineral nutrients from the site (Schlesinger *et al.* 1990). The soil-binding properties of plant roots are especially critical in dunes, where species that can stabilize sediments serve a critical role in determining ecosystem structure (e.g. Klopatek and Stock 1994). Harvesting or loss of these species may shift a stable substrate (offering habitat for plant and animal populations) to a much harsher migrating dune system. Disruption of a microbial 'crust' on the soil surface (e.g. by hooves) alters inputs of nitrogen by these N-fixers (see 6.1.4.8). Burrowing animals (termites, ants, rodents, marsupials) create and reinforce heterogeneity in soil structure and nutrients (Whitford 1993).

6.1.4.4 Water distribution, balance and quality

Human impacts on biodiversity. Human and livestock activity have altered plant species composition and vegetation cover in many regions, both by reducing native vegetation and by introducing non-native species, either deliberately or accidentally. Aquatic habitats (riparian zones, springs) have been especially vulnerable to invasions of non-native plants. Populations of burrowing organisms have also been reduced. Road construction and other activities have altered drainage patterns, with resulting changes in water distribution and hydrologic regimes: these changes then impact the distribution and behaviour of organisms.

Ecosystem consequences of impacts. Vegetation cover modulates the impact energy of raindrops, reducing the amount of sediment dislodged and transported during heavy storms (Wood *et al.* 1987; Rogers and Schumm 1991). Rooted plants provide root channels which in turn enhance deep percolation of water into the soil profile (e.g. Greene 1992), and the nature of the plant canopy influences the proportion of rainfall that is intercepted and that falls either as throughfall or stem-flow (West and Gifford 1976; Navar and Bryan 1990; Tromble 1987). Deep roots of shrubs, and transpirational losses, are a strong influence on soil water content in the lower parts of the soil profile and thus on the depth of carbonate deposition, leading potentially to alterations in the effective rooting depth of the soil (Schlesinger *et al.* 1987). Removal of shrubs would then be expected to have potentially strong effects on soil moisture content and other characteristics. On the other hand, Dugas and Mayeux (1991) and Carlson *et al.* (1990) found that increased herbaceous cover following shrub removal resulted in little net change in water distribution or in total evapotranspiration from dry rangeland sites over the short term. Introduction of phreatophytic (deep-rooted)

plants, especially the genus *Tamarix*, has dramatically altered hydrology in some riparian systems (Blackburn *et al.* 1982), even leading to the elimination of surface water from previous spring sites due to its high evapotranspiration). Reduction in populations of termites (small burrowing animals) has a dramatic influence on infiltration and surface runoff (Elkins *et al.* 1986).

6.1.4.5 Feedbacks to atmospheric properties

Human impacts on biodiversity. At the global scale, human activity is expressed primarily through direct and indirect alterations of vegetation cover and disturbance of the soil surface.

Ecosystem consequences of impacts. Vegetation cover is negatively associated with albedo. Arid lands are significant determinants of the Earth's overall albedo (Otterman 1989) and thus of its global radiation balance. Arid lands are also significant contributors of dust, and reductions in vegetation cover caused by grazing or other human activity (e.g. roads) increase these contributions (Pewe 1981; Pye 1987). While it has been proposed that arid-zone termites contribute substantial amounts of methane to the atmosphere, recent work suggests that arid regions are actually a significant sink for methane (Striegl *et al.* 1992). Conversion of semi-arid grassland to shrubland or woodland may increase carbon storage, affecting the global carbon cycle (McPherson *et al.* 1993).

6.1.4.6 Landscape structure

Human impacts on biodiversity. Human alterations to semi-arid landscapes are generally to facilitate grazing by livestock: they include fencing of pastures or paddocks, creation of new water points for animals, and construction of roads or trails for transport. Human and livestock activity often creates gradients of disturbance or of alteration (a 'variegated' landscape), rather than the conspicuously patchy or fragmented nature of landscapes in other ecosystem types (McIntyre and Barrett 1992).

Ecosystem consequences of impacts. Creation of new watering points has perhaps increased local rates of NPP. Conversely, disruption of normal drainage patterns (e.g. by road construction or by diversion of water) alters the hydrology of intermittent streams and playas, and decreases the productivity of vegetation dependent on that water flow (Schlesinger and Jones 1984).

6.1.4.7 Biotic linkages and species interactions

Human impacts on biodiversity. Importation of non-native plants for improvement of forage or as weeds in some regions has reduced local plant diversity by replacing native species. Humans have attempted direct removals of plant species considered to be undesirable forage species (e.g. large-scale removals of native shrubs in southwestern US rangelands). Populations of some tree species in semi-

arid regions have been depleted by heavy use for fuel or other purposes. Populations of native mammals have been reduced either intentionally, when these are viewed as competitors for forage or as possible predators of livestock, or indirectly, e.g. through the effects of insecticide use on bat populations.

Ecosystem consequences of impacts. Alteration of native to non-native grass cover has apparently reduced populations of native ants and other consumers in Arizona (Whitford, pers comm). There is also some evidence that declining bat populations in the southwestern states of the USA have led to decreased frequency of effective pollination in some bat-pollinated monocarpic species of *Agave* (Howell and Roth 1981). Many biotic interactions in arid lands are less direct, however, resulting from the modification or modulation of the harsh environment by one species in such a fashion as to facilitate the occurrence or reproduction of other organisms. Among plants this facilitation is described as the 'nurse plant' phenomenon. The regeneration of one species under another might create a cyclic replacement or successional series (McAuliffe 1988; Yeaton and Esler 1990; Gutierrez *et al.* 1993): there are many reports that the presence of one plant species creates a specific environment that facilitates the establishment of other particular species (e.g. Montaña 1992; Silvertown and Wilson 1994). The loss of large woody species for use as fuel or as carving material has been suggested as a negative influence on the persistence of many typical species of desert plants (e.g. Franco and Nobel 1989). Introductions of large animals (as game or livestock) have often established wild or feral populations (horses, camels, oryx) that affect native vegetation and compete with native herbivores.

6.1.4.8 Microbial activities

Human impacts on biodiversity. The most prominent and conspicuous arena of microbial activity is the formation of crusts on the soil surface by algae, cyanobacteria and lichens (Isichei 1990; West 1990). Introduction of hoofed grazers has reduced the prevalence and development of these crusts in many regions (West 1990).

Ecosystem consequences of impacts. Microbial crusts play significant roles in nitrogen cycling and in stabilizing the soil surface against erosion (Eldridge and Greene 1994). In some cases these microbes secrete polysaccharides that absorb water, increasing the effective infiltration of precipitation; in other cases the secretions are actually hydrophobic, reducing soil wetting. Reductions in soil crusts are assumed to have reduced nitrogen fixation, increased soil erosion, and altered local infiltration of moisture.

6.1.4.9 Summary and relevance to human activities

Human alterations of biodiversity in desert regions have been mediated chiefly by the management of semi-arid and

arid regions for livestock use and by the importation of non-native plants. Arid regions are a reservoir of genetic variation useful for the development of new crops and new varieties of existing crops better suited to agriculture in marginal environments (e.g. Glenn *et al.* 1991). Because biological activity plays such an important role in moderating the harsh environment of arid regions, alteration of biodiversity is expected to have negative feedbacks on the remaining biological components of the system. These feedbacks lead to the formation of alternative stable states of the system, with stronger control by abiotic forces (Schlesinger *et al.* 1990), and the necessity for management strategies focused on transitions between states (Westoby *et al.* 1989).

6.1.5 Tropical savannahs

6.1.5.1 Introduction

Savannahs are tropical ecosystems ‘...forming a continuum of physiognomic types ranging from closed woodlands with a heliophytic grass understorey, through open savannah woodlands to treeless edaphic grasslands’ (Huntley and Walker 1982). In all these areas, grasses with the C4 photosynthetic pathway dominate the herbaceous layer while the woody component, at the moist end of the moisture gradient, comprises fire-tolerant trees and shrubs. With an estimated area ranging from 15 to 24.6×10^6 km² (Whittaker and Likens 1975; Olson *et al.* 1983) savannah ecosystems constitute the largest single type of terrestrial biome. Savannahs develop in soils of generally low fertility, under a regime of strongly seasonal rainfall, and are submitted to recurrent disturbances through herbivory and fire (Figure 6.1-1) (Sarmiento 1984; Scholes and Walker 1993). These environmental constraints largely determine structure and productive capacity of these ecosystems (Walker 1987; Detling 1988). Population reductions due to disturbance, and spatial patchiness, contribute to the maintenance of species and functional group diversity (Huston 1979). Lowering perturbation frequency results in a large accumulation of litter leading to a reduction in diversity of the grass layer (Tilman 1993). However, diversity of the tree layer increases in the absence of perturbation due to the survival of fire- or grazing-sensitive species (San José and Fariñas 1991).

6.1.5.2 Human impacts on biodiversity

Human intervention in tropical savannahs has been continuous throughout human history: thus it has been present in Africa longer (around 500 000 years), than in Australia (c. 40 000 years) and South America (c. 12 000 years). Human modification of savannahs occurs through the utilization of fire for hunting, and the grazing of domesticated herbivores. Human invasions have been associated with large-scale megafauna extinctions in South America during the Pleistocene (Martin 1973). Massive modifications of landscape are, however, relatively recent, beginning with the arrival of European settlers. Most changes are related to the agricultural utilization of grasslands, and the largest human impacts on biodiversity

Figure 6.1-1: Savannahs of the world. The Andropogonoid grasses dominate the core savannahs in the 500–2000 mm rainfall zone. Humid savannahs with heavier soils are dominated by Eragrostoid, Aristidoid and Chloridoid grasses. The former are more common in South America, while the latter are found in Africa, Australia and South America. Within the core savannahs, woodlands occupy the medium light-textured and more freely drained soils characterized by *Eucalyptus* woodlands in Australia, the *Brachystegia*, *Isobertinia* and *Julbernardia* woodlands of Africa, and the *Curatella*–*Byrsonima* woodlands of South America. Savannah parklands occupy the medium to heavy textured soils in both Africa and Australia. The woody stratum is characterized by leguminous genera (*Acacia*, *Bauhinia*/*Lysiphyllum*) and *Terminalia*. On heavy cracking clay soils, trees and shrubs are rare. There are savannahs at altitudes above 800–1000 m in Africa and South America. The *Cerrado* region in Brazil contains possibly the largest diversity of woody species in tropical savannahs. (Slightly modified from Johnson and Tothill 1985.)

are related to the introduction of cattle; the over exploitation or overprotection of large native herbivores, and the introduction of alien grasses and legumes (Laws 1970; Hatton and Smart 1984; Mott 1986; Owen-Smith 1988; Braithwaite *et al.* 1989; Braithwaite 1990; Freeland 1990; Holmes and Mott 1993; Klink *et al.* 1993; Young and Solbrig 1993).

6.1.5.3 Productive capacity, biomass and decomposition

Reductions in diversity of primary producers lowers both resistance to grazing by a single species of ungulate and resilience after grazing, thereby decreasing biomass stability through the seasons. Changes in the composition and density of ungulates affect primary productivity because herbivory regulates competition between plant species through maintenance of an open canopy, conservation of soil moisture and nutrient recycling. The ecological properties of the plant species have important consequences for ecosystem organization and they appear not to be interchangeable (McNaughton 1985, 1994). Ruminant (e.g. zebra) and non-ruminant (e.g. wildebeest)

ungulates graze seasonally in grasslands with a high proportion of nutritious species. These plant species assemblages are more likely to occur in grasslands of higher diversity, and therefore support more herbivores (Ben-Shahar and Coe 1992). Diverse natural grasslands seem to be more resilient to drought-induced changes in productivity than simplified systems developed through long-term fertilization (Frank and McNaughton 1991; Tilman and Downing 1994). Changes in biodiversity in Australian and South American savannahs have affected biogeochemical cycles leading to habitat and landscape deterioration. The planting of exotic grasses with high production capacity is frequently followed by a reduction in yield and quality of forage due to slower mineralization of humic material and turnover of nitrogen in plant residues with high lignin:nitrogen ratios, and the gradual loss of nitrogen from animal excreta (Holmes and Mott 1993; Klink *et al.* 1993).

6.1.5.4 Soil structure and nutrients

Introduction of African grasses into South American and Australian savannahs increases biomass production per unit area, allowing larger numbers of cattle to be grazed per unit of land. Higher cattle density reduces soil permeability and vegetation cover, and leads to increased runoff and erosion (Mott *et al.* 1979; Seiny-Boukar 1992). Grazing-intolerant native grasses are being replaced by faster growing, invasive grasses (Mott *et al.* 1979; Holmes and Mott 1993). In dry years overgrazing destroys the grassland allowing the penetration of woody weeds, and resulting in extended erosion (Winter 1990). Exclusion of large herbivores in East Africa reduced overgrazing and resulted in tree regeneration and a significant increase in soil fertility (Hatto and Smart 1984), while introduction of legumes improved nitrogen availability in Australian grasslands (Henzell 1968; Myers and Robbins 1991). Higher palatability of legumes, and patchy distribution in pasture, leads to increased trampling and soil deterioration strongly affecting pasture productivity in the short term (Mott *et al.* 1979).

6.1.5.5 Water distribution, balance and quality

Large-scale agricultural utilization of savannahs either changes the composition of primary producers (native grasses are substituted by alien grasses and legumes for intensified cattle production), or eliminates the plant cover for planting of cash crops (soybean, peanuts, sugar cane, etc.). In both cases savannah soils require a heavy input of fertilizers leading to long-term impacts on water quality (pollution of underground water resources and rivers) (Mott *et al.* 1979; Gillard *et al.* 1989; Seiny-Boukar *et al.* 1992).

6.1.5.6 Atmospheric properties

Periodic burning of savannah landscapes reduces tree/grass ratios (Medina and Silva 1990) and has implications for

atmospheric chemistry (Lobert *et al.* 1990). There are potential strong feedbacks between the species composition of grasslands and nitrogen cycling. Grass species differ in below-ground biomass accumulation and tissue-nitrogen and lignin concentrations, and these factors affect nitrogen mineralization rates (Wedin and Tilman 1990). Grass species also differ in their nitrogen requirements depending on their mode of photosynthetic C4 pathway. Malate formers seem to require less nitrogen and have lower tissue-nitrogen concentration, while aspartate formers require more nitrogen and are more palatable (Huntley 1982). The relative proportion of these photosynthetic types may therefore affect nitrogen losses through fire and the rate of nitrogen mineralization in soils. Changes in soil nitrogen availability modify substantially the relative proportion of malate and aspartate formers in South African grasslands (Medina and Huber 1992). The rapid transition from *miombo* woodland and savannah to maize-based agriculture in southern Africa results in an almost complete loss of ecosystem carbon pools. Clearing of the *miombo* and establishment of maize-based agriculture on a sandy alfisol resulted in a decline in total soil organic carbon from 28 to 9 Mg/ha (Woomer 1993).

6.1.5.7 Landscape and waterscape structure

Habitat heterogeneity determined by the co-occurrence of trees and grasses in savannahs is considered to be a key factor for the maintenance of their biodiversity (Gillard *et al.* 1989; Holmes and Mott 1993). Utilization of savannah lands for grazing has modified their original fire regimes. Natural savannah fires have a low frequency because they depend on the occurrence of dry electrical storms, but fire frequency has been increased under human influence in order to prevent excessive fuel accumulation and to provide green forage for cattle during the dry season. As a result, tree/grass ratios have changed markedly. Trees are more sensitive to fire than grasses, because the latter accumulate most of their biomass and nutrient resources below ground. High fire frequency reduces the number of tree species, and the numbers of individuals per species in most savannah sites (San José and Fariñas 1991; Dauguet and Menaut 1992).

6.1.5.8 Biotic linkages and species interactions

The co-occurrence of trees and grasses in savannahs results in patchiness of resource availability. Changes in tree/grass ratios significantly modify rates of biogeochemical and energy cycling as a result of the contrasting characteristics of the two components with respect to light interception and nutrient requirements (Kellman 1979; Georgiadis 1989; Ben-Shahar 1991; Isichei and Muoghalu 1992; Belsky *et al.* 1993; Mordelet *et al.* 1993). The recent human population explosion in Africa, and the migratory constraints imposed by political boundaries, increased the occupation of land with a consequent restriction of the

ranges of wild animals. Most of the formerly wooded southern section of the Murchison Falls National Park (Uganda), c. 2600 km², has been converted from woodland into grassland (Hatton and Smart 1984). Numbers of elephants in Tsavo National Park increased dramatically after the Second World War as a result of the enforcement of anti-poaching activities, and the consequent overpopulation of elephants resulted in habitat deterioration, particularly along waterways. Under the influence of elephants and fire the dry *Commiphora*–*Acacia* bush has been destroyed over large areas and replaced by grassland (Laws 1970; Owen-Smith 1988). In the same area, a long-term experiment excluding herbivory by large ungulates resulted in a marked tree regeneration, and a pronounced increase in soil fertility (Hatton and Smart 1984).

Vegetation-herbivore interactions are highly varied. In eastern Africa herbivory patchiness can be associated with nutritional quality of the forage, but also grazing animals can modify plant nutritional properties through their influence on soil nutrient availability and plant species composition (McNaughton 1985; Georgiades and McNaughton 1990). Although savannahs of northern Australia and South America evolved in conjunction with herbivore pressure, their herbivore megafauna disappeared in the Pleistocene (Martin 1973). Europeans introduced several medium- and large-sized herbivore species, in numbers comparable to those of native herbivores elsewhere. In Australia, due to the lack of predators and pathogens, the density of feral populations of introduced herbivores is much larger than in their original habitats, and the high density of herbivores has led to ecosystem deterioration (Freeland 1990). Mutualistic relationships in Australian ecosystems have frequently evolved presumably in response to low resource availability. Australasian woody plants produce copious quantities of nectar, and this has had a pronounced effect on the fauna. Forty-two percent of the honey-eater species of the family Meliphagidae occur in Australia, and most of the rest are found in New Guinea (Braithwaite 1990). The potential damage for tree reproduction following reductions in honey-eaters' diversity is large. Pasture improvement and tree clearances have produced substantial reductions in the number and frequency of native herbaceous species, but also of bird species and soil invertebrates (Greenslade 1992). Thinning of bird populations has been associated with the spread of eucalyptus dieback (rural dieback) caused by more intensive defoliation by insect herbivores.

6.1.5.9 Microbial activities

Mycorrhizae play an important role in nutrient uptake, and possibly also water uptake, by vascular plants. C4 plants in nutrient-poor soils appear to be more dependent on mycorrhizal symbiosis than are C3 plants (Hetrick *et al.*

1990), both at the seedling stage and during regrowth from rhizomes. Mycorrhizal abundance in grasslands is generally inversely related to soil fertility and positively related to the ratio of plant to soil nutrient contents (McNaughton and Osterheld 1990). Therefore, mycorrhizal associations are thought to stabilize ecosystem nutrient fluxes. The semi-arid savannahs in Botswana (rainfall 500 mm) have been degraded by overgrazing, so restoration depends on the probability of inoculation of seedlings' roots (Veenendaal *et al.* 1992). Populations of mycorrhizae in the soil can be managed by the introduction of spores of species differing in their host selectivity and efficiency in phosphorus uptake capacity (Dodd *et al.* 1990). Changes in ecological conditions leading to modifications in the mycorrhizal fungi may result in disturbances of the phosphorus availability for native grasses. Introduction of legumes improves nitrogen supply to the vegetation through symbiotic nitrogen fixation (Henzell 1968). Plant growth in eastern African grasslands induced by rainfall events is accompanied by strong pulses of microbial activity, and the concentration of large herbivores attracted by the green foliage. Therefore, soil microbial activity is closely correlated with patterns of herbivore use and intensity of herbivory in natural grasslands of eastern Africa (Ruess and Seagle 1994).

6.1.5.10 Summary and relevance to human activities

Savannah ecosystems have been profoundly modified throughout human history. Most modifications are related to overpopulation and mismanagement of natural resources. Reductions in landscape, community, and species diversity have affected ecosystem functioning as expressed by habitat deterioration and diminished capacity of savannah environments to support human populations. Erosion, pollution of water sources, reductions in soil fertility and diminished carrying capacity for herbivores are some of the ecological consequences relevant for the continued use of these environments. Restoration of ecosystem functioning through the recovery of biodiversity is an essential step in the planning of sustainable use of savannahs.

6.1.6 Boreal forests

6.1.6.1 Introduction

The boreal forest is a circumpolar biome covering approximately 13×10^6 km² in upland forest and 2.6×10^6 km² in peatland in North America and Eurasia (Olson *et al.* 1983; Shugart *et al.* 1992; Apps *et al.* 1993). Although ecosystems in this biome are generally species-poor, many species respond to and affect resource availability, food supply for herbivores, and disturbance regimes in very different ways (Bryant and Chapin 1986; Payette 1992; Pastor and Mladenoff 1992). Functional diversity is therefore high, but each functional group is represented by only a few species. These strong feedbacks between species life traits, resources and disturbance regimes may in turn cause cyclic fluctuations in populations of animals (Hansson 1979; Haukioja *et al.* 1983). Plant tissue chemistry integrates biodiversity with ecosystem properties. Tissue chemistry varies not only

between species but also between biogeographic provinces of major plant species (Bryant *et al.* 1989, 1994). Tissue chemistry controls decomposition and nutrient availability, palatability and flammability (Bryant and Chapin 1986; Pastor and Mladenoff 1992; Pastor and Naiman 1992) and is correlated with life form, growth rates and longevity (Chapin 1986; Bryant and Chapin 1986).

6.1.6.2 Human-induced impacts and threats to biodiversity

Increased atmospheric loadings of radiatively active gases, with consequent warming of the climate, and logging are the two human activities with great consequences for changes in biodiversity and ecosystem properties in boreal regions over the next several decades. Initially, these societal impacts will alter the diversity of tree species. Because of the couplings between tree species, food web structure, nutrient cycling and the atmosphere, these changes in tree species composition ramify throughout the ecosystem and biome. The probability of climate warming and increased logging over the next several decades is high, but the ecosystem effects of these impacts are greatly conditioned by the functional group affected and local conditions. Human-induced changes in biodiversity in boreal regions therefore introduce high variance in ecosystem properties at local and regional scales.

6.1.6.3 Productive capacity, biomass and decomposition

Human impacts on biodiversity. Global warming will cause differential migration of tree species northward from the boreal zone into the tundra, and from grasslands and northern hardwood areas into areas currently occupied by boreal trees (Pastor and Post 1988; Davis and Zabinski 1992; Pastor and Johnston 1992). Logging in the boreal forest generally consists of clear-cutting or plantation establishment. Clear-cutting alone perpetuates early successional forests dominated by shade-intolerant hardwoods, but with generally high species richness, while plantations consist mainly of monocultures of conifers (Mladenoff and Pastor 1993; Haila 1994).

Ecosystem consequences of impacts. As the climate warms, the differential migration of tree species changes productivity, biomass and decomposition (Payette *et al.* 1985; Pastor and Post 1988; Bonan *et al.* 1990; MacDonald *et al.* 1993). The direction of change depends on the local distribution of soil types. On sandy soils in mid-continental regions south of the permafrost line, drought stress will increase and the boreal forest will be replaced by a jack pine–oak savannah of low productivity and slow decomposition. On clay soils that can retain water, the boreal forest will be replaced by northern hardwoods of higher productivity and decomposition rates (Pastor and Post 1988). In far northern regions, the local distribution of permafrost affects how ecosystems respond to climate warming because of differential sorting of species (Bonan

et al. 1990). Similarly, forestry practices can increase productivity and biomass where they favour rapidly growing hardwoods or where plantations of slow-growing conifers are fertilized (Mladenoff and Pastor 1993); however, the increased productivity in monoculture plantations comes at the expense of local species richness.

6.1.6.4 Soil structure and nutrients

Human impacts on biodiversity. The shifts in relative abundance of hardwoods and conifers through logging and climate warming noted above affect soil structure and nutrients through changes in the amounts and arrays of litter returned to the soil (Flanagan and van Cleve 1985; Pastor and Mladenoff 1993).

Ecosystem consequences of impacts. Where abundances of hardwoods increase, soil nutrient availability will also increase because the chemistry of litter from these species makes them easily decomposable (Flanagan and van Cleve 1983; Pastor and Post 1988; Pastor and Mladenoff 1993). In contrast, increased abundances of conifers on droughty soils in a warmer climate or in monoculture plantations will cause declines in soil nutrient availability because of the high lignin and low nutrient contents of their litter. These changes in nutrient availability will then feed back and affect productivity and biomass because of nutrient limitations to growth (Pastor and Post 1988; Pastor and Mladenoff 1993).

6.1.6.5 Water distribution, balance and quality

Human impacts on biodiversity. Climate warming will have the greatest effect on water distribution by changing the relative abundance of conifers and hardwoods and thus altering regional evapotranspiration rates, and by causing melting of permafrost in far northern regions.

Ecosystem consequences of impacts. The ecosystem consequences of the effects of altered biodiversity on the hydrologic cycle are less well studied than for other ecosystem processes. However, widespread melting of permafrost will certainly alter large-scale drainage patterns (Post 1990) with consequent region-wide impacts on water quality and river flows.

6.1.6.6 Feedbacks to atmospheric properties

Human impacts on biodiversity. By altering the relative abundance and distribution of functional groups, climate warming and logging will change the carbon balance of ecosystems. Furthermore, warming of the soils of peatlands and other northern wetlands will change the amount and types of trace gas loadings through changes in the microbial community (Gorham 1991).

Ecosystem consequences of impacts. Boreal regions contain large portions of the global carbon pool. Currently this biome is probably a net sink for carbon, but upon warming it can be converted to a net source (Post 1990;

Apps *et al.* 1993). Warming of the soils, particularly in wetlands, can increase trace gas loadings, especially that of methane (Gorham 1991). However, the net increase in trace gas loadings, and the balance of methane versus carbon dioxide, depends on the types of plant communities and the ease of decomposition of the soil or sediment organic matter (Roulet *et al.* 1992; Updegraff *et al.* 1994). Logging can increase productivity and thereby offset the net export of carbon, but only if rotations are long enough to allow the biomass to recover completely to achieve that in old-growth forests. If logging causes large losses of conifers over large areas, the albedo of the boreal region may increase and therefore its role in the heat and water budgets of the Earth may also be seriously changed (Bonan *et al.* 1992).

6.1.6.7 Landscape structure

Human impacts on biodiversity. By changing the relative distribution of stands composed largely of one functional group or another, both climate warming and logging alter the structural patterns of landscapes with consequent effects on the fauna that depend on them. Furthermore, climate warming can have secondary effects on landscape structure by increasing fire frequency and intensity (Clark 1989; Payette 1992).

Ecosystem consequences of impacts. Besides the impacts on productivity, nutrient cycling and atmospheric feedbacks noted above, changes in landscape structure have significant effects on habitat for important groups of fauna. By homogenizing stand and landscape structure and composition, logging has severe consequences for the diversity of those faunal groups — particularly avian and insect fauna — that depend on old-growth stands, microsite habitats, and a diversity of habitat elements (Jarvinen and Vaisanen 1977, 1978; Jarvinen *et al.* 1977; Helle 1984; Virkkala 1987, 1991; Telfer 1992). Fairly subtle changes in habitat structure can have large ecological consequences if they occur uniformly over large areas (von Haartman 1973; Jarvinen *et al.* 1977; Haila *et al.* 1980; Helle and Jarvinen 1986). Because many breeding birds are neotropical migrants, this loss of habitat has important consequences for tropical forests as well.

6.1.6.8 Biotic linkages and species interactions

Human impacts on biodiversity. Climate warming and logging will indirectly affect herbivore–ecosystem interactions by altering the relative abundance of plants used as food and, for mammalian herbivores, those used as cover. However, the herbivores themselves can alter the relative abundance of species, thus introducing strong feedbacks into the changes in biodiversity caused by human activities.

Ecosystem consequences of impacts. Browsing by moose (*Alces alces*) and other large ungulates changes the relative composition of the plant community from highly browsed

hardwoods with high litter quality and decay rate to unbrowsed conifers with low litter quality and decay rate (Bryant and Chapin 1986; Pastor *et al.* 1993a). Thus, heavily browsed areas have lower nutrient availability as conifers invade (Pastor *et al.* 1993a). Food quality is related to secondary chemistry and there is growing evidence that there are longitudinal gradients of palatability at the subspecies level across entire continents (Bryant *et al.* 1989, 1994). Changes in the relative abundance of aspen affect habitat for beaver, which in turn affects the abundance, diversity and distribution of wetlands created by this important keystone species (Johnston and Naiman 1990; Pastor *et al.* 1993b). Increased probability of insect outbreak can also be induced by increased drought upon climate warming (Mattson and Haack 1987; Holling 1992). There is therefore the very strong likelihood that climate and logging-induced changes in biodiversity and ecosystem functioning will be strongly conditioned by secondary feedbacks through herbivores and the entire food web.

6.1.6.9 Microbial activities

Human impacts on biodiversity. Human impacts on the microbial community and its activities are mediated primarily through changes in litter quality and quantity, with changes in the relative distribution of plant functional groups, and through changes in soil temperature and water balance.

Ecosystem consequences of impacts. The changes in nutrient cycling rates and trace gas loading to the atmosphere discussed above are all mediated through changes in the microbial community. The diversity of the microbial community appears to be more important in determining the relative proportion of trace gases and forms of inorganic nutrients than in determining the mass balance of carbon and nutrients through the soil (Roulet *et al.* 1992; Updegraff *et al.* 1994).

6.1.6.10 Summary and relevance to human activities

Properties of boreal ecosystems can change rapidly with changes in species composition, whether because of natural succession (Wien and El-Bayoumi 1983; Pastor and Mladenoff 1992; Payette 1992); herbivory (Bryant and Chapin 1986; Pastor *et al.* 1993); human-induced changes through climate warming (Pastor and Post 1988; Bonan *et al.* 1990), or logging (Mladenoff and Pastor 1993a; Haila 1994). The loss of a few species can therefore have significant consequences for ecosystem functioning, but the direction of change depends to a great extent on the functional group to which the species belongs.

6.1.7 Temperate grasslands

6.1.7.1 Introduction

Grasslands are the potential natural vegetation on approximately 25% (33×10^6 km²) of the land surface of the Earth (Shantz 1954), although estimates of their current extent range from 16% (Whittaker and Likens 1975) to 30% (Ajtay *et al.* 1979).

Three aspects of grassland environments distinguish them from other ecosystem types (Anderson 1982; Milchunas *et al.* 1988): these are drought, fire and grazing by large ungulate herbivores. All three factors provide selection pressures favouring high turnover of above-ground plant organs, location of perennating organs near the soil surface, and location of a large fraction of plant biomass and activity below ground. Drought is a frequent influence on dry grasslands: fire is a much more significant force in shaping grasslands in humid regions than it is in dry regions. Grazing can be an important evolutionary force across the moisture gradient but its specific influence depends upon the moisture status of the site (Milchunas *et al.* 1988). Adaptations that enhance survival in arid and semi-arid environments may promote tolerance or

avoidance to grazing (Coughenour 1985). Therefore, grazing should have a larger effect on the species composition in humid than in arid and semi-arid grasslands (Milchunas *et al.* 1988).

6.1.7.2 Human impact on biodiversity

The most common use of grasslands is for grazing by domestic animals to produce mainly meat, milk and fibre. The first management action in most cases has been to replace native grazers and their predators with a few species of domestic animals. In an attempt to enhance animal production, humans have tried to increase primary production and/or animal consumption. Techniques aimed at increasing primary production, such as fertilization and irrigation, are all practices that raise resource availability for plants. Given that domestic animals have a selective intake, a large fraction of management techniques attempts to change species composition to match domestic animal preference. By their selective grazing behaviour, livestock tend to modify species composition in opposition to the efforts of managers. Even minimum husbandry has resulted in significant increases in animal biomass density in vast grassland regions (Oesterheld *et al.* 1992).

Grazing does not necessarily reduce plant biodiversity although overgrazing can result in losses of diversity at the population, species, ecosystem and landscape levels. The lack of grazing in some grassland types also results in biodiversity losses (Sala *et al.* 1986; Sala 1988). In general, ecosystem enrichment via fertilization or irrigation results in a decrease in diversity at the population and species levels (Tilman 1993). The replacement of animal or plant species by introduced species has a clear and direct negative effect on biological diversity. Changes in ecosystem and landscape diversity occur as a result of habitat selection by livestock (Smith *et al.* 1992) and replacement of native ecosystems by cultivated grasslands and croplands (Burke *et al.* 1991).

6.1.7.3 Productive capacity

Human impact on biodiversity. Primary production is most often manipulated by the addition of water or mineral nutrients. Both kinds of resource additions directly and indirectly modify biodiversity (Rosensweig 1971; Mellinger and McNaughton 1975; Lauenroth *et al.* 1978; Tilman 1993).

Ecosystem consequences of the impacts. A decrease in species richness, with initial deletion of the rarest species, results in no change in primary production until a threshold is reached beyond which there is a steady and substantial decrease in production (Figure 6.1-2). Removal of rare species in the Serengeti grasslands resulted in full compensation of production by the remaining species (McNaughton 1983). Deletion of species of intermediate

Figure 6.1-2: The effect upon primary productivity (P_n) of removing species that have different biomass in the intact ecosystems. In each case, all the individuals of a different species were removed. Remaining species were able to compensate for the removal of species with small biomass but were not able to compensate for the removal of the most abundant species (From: McNaughton 1983).

abundance resulted in production being only partially compensated. Finally, removal of dominant species resulted in a significant decrease in production.

Grasslands provide several examples in which the relationship between diversity and primary production has been assessed experimentally. The sites studied are geographically diverse and include California annual grasslands, old fields in New York, and grasslands in the Serengeti (McNaughton 1993). Results are contradictory: a negative relationship was observed between productivity and biodiversity in the annual grasslands of California and in the old fields of New York, whereas no relationship between productivity and diversity was found in the Serengeti. The effects of species diversity on production should be assessed with reference to which species have been deleted, and with respect to the driving forces behind the observed changes in diversity, rather than the diversity itself. In the case of the Serengeti, differences in diversity resulted from differences in grazing regime, while in the old fields in New York the diversity differences were a consequence of a successional process.

The diversity–stability hypothesis (McNaughton 1977) suggests that perturbations will result in a larger change in

ecosystem functioning in simple systems than in diverse systems. There is experimental evidence to test this hypothesis in grasslands. McNaughton (1993) analysed the response to a perturbation caused by fertilization along a diversity gradient which emerged as a result of a successional process. Similarly, Tilman and Downing (1994) analysed the response to a perturbation caused by a severe drought along a diversity gradient resulting from an experimental nitrogen fertilization where diversity was maximum in the native system and decreased as fertility increased (Figure 6.1-3). In both cases, the effect of perturbation on production was at a maximum in the simple systems and a minimum in the most diverse systems. The conclusions emerging from the experiment which used a diversity gradient created by differential fertilization has been criticized because greater soil fertility generally favours plants with lower root: shoot ratio, higher leaf conductance, and greater photosynthetic capacity (Givnish 1994). These characteristics also result in lower drought resistance. Therefore, the largest effect of drought observed in low diversity plots could have been the result of those plots being dominated by drought sensitive plants. The critical experiment to address this question has not been done yet: it would compare the response to similar perturbations of ecosystems with different levels of natural or experimentally created diversity, and should disentangle the effect of diversity from the effect of individual species.

6.1.7.4 Decomposition and soil structure

Human impact on biodiversity. Range managers use chemical, fire and mechanical means to modify plant species composition by deleting those species that are least preferred by domestic animals or by adding those that are highly preferred. Selective grazing by domestic herbivores also modifies plant species composition.

Ecosystem consequences of the impacts. The effects of biodiversity on decomposition in grasslands can be viewed from the plant perspective or the microbial perspective. Microbial diversity is not well documented in grasslands and its effect on decomposition is even less clearly understood. The effects of plant species diversity on decomposition result mainly from differences in litter quality among species. Several experiments have demonstrated the importance of species characteristics to total soil nutrients, nutrient availability and the rate of decomposition (e.g. Wedin and Tilman 1990; Matson 1990; Hobbie 1992; Vinton and Burke in press).

6.1.7.5 Water distribution and balance

Human impact on biodiversity. Management manipulations and foraging behaviour may change biodiversity. Large areas of grasslands in North America and Africa have slowly changed into shrublands and savannahs presumably as a result of grazing (Buffington

Figure 6.1-3: The effect of plant species richness before a severe drought on above-ground biomass during the drought year expressed as a fraction of previous year biomass. Standard error and number of plots with a given species richness are shown. The gradient of species richness was experimentally created by fertilization (from: Tilman and Downing 1994).

and Herbel 1965; Walker *et al.* 1981; van Vegten 1983; Neilson 1986; Archer 1989).

Ecosystem consequences of the impacts. Important input and output flows, which determine water balance and distribution of water, change with the scale of the unit under consideration. At the ecosystem level, the major flows are transpiration, bare soil evaporation, deep percolation, run-on, run-off and precipitation. At the plant level, transpiration is the only relevant flow but at higher levels of organization, watershed variables become dominant. All the output flows of water at one scale are intimately related, and although the biotic components directly affect mainly absorption and transpiration, they affect all other components of the water balance indirectly.

Reduction of transpiration as a result of species deletions is related to species-specific characteristics that affect water dynamics. Rooting depth, phenology, maximum transpiration rate, drought resistance or avoidance are all species characteristics that affect water balance. Species with deep roots are able to absorb water from a different part of the soil profile than species with shallow roots. Species with different phenological patterns (early vs late season) are able to use water available at different times of the year. In addition, many of these characteristics are self-associated. For example, late season phenology is associated in several systems to xerophytism or deep root systems (Gulmon *et al.* 1983; Golluscio and Sala 1993).

Experiments and associated models of grassland water dynamics have shown how removal of functional types such as perennial grasses or shrubs results in profound

alterations of the ecosystem water balance (Knoop and Walker 1985; Paruelo and Sala 1995). Deep percolation losses increase as a result of a decrease in the abundance of one of the functional types and the distribution of water in the soil profile changes as a result of deleting deep or shallow root functional types. Only a fraction of the water freed by the removal of a functional type is used by the remaining functional type (Sala *et al.* 1989). Most of these experiments focused on the deletions of entire functional types, providing no experimental evidence for the effects of deleting individual species.

6.1.7.6 Atmospheric properties

Human impact on biodiversity. Range management results in changes in biodiversity as described previously.

Ecosystem consequences of the impacts. Atmospheric CO₂ is an important trace gas and a major component of the carbon cycle. We have described how biological diversity at scales ranging from species to landscapes affects production and decomposition which are the major processes driving the carbon cycle. We are not aware of any studies relating species diversity to atmospheric properties. However, Burke *et al.* (1991) calculated the effects on the carbon balance of converting a large fraction of the North America Central Grassland Region into cropland. Cultivation resulted in a net release of carbon from soil organic matter larger than the expected loss as a result of climate change. The current increase in atmospheric methane is not related to an increase in the number of grazing mammals (Crutzen *et al.* 1986).

6.1.7.7 Landscape structure

Human impact on biodiversity. Croplands have expanded dramatically during this century, from 9.1×10^6 to 15×10^6 km² (Richards 1990). This expansion has altered landscape heterogeneity in grasslands. Habitat selectivity by domestic livestock has differentially influenced riparian ecosystems and therefore altered landscape diversity. Domestic livestock, and especially cattle, tend to congregate in the topographically lowest portions of the landscape (Senft *et al.* 1985; Pinchak *et al.* 1991). Such habitat selectivity has negative effects on the plant and animal diversity of riparian ecosystems (Kauffman and Krueger 1984; Smith *et al.* 1992).

Ecosystem consequences of the impacts. The reduction in diversity of streamside vegetation and its productivity have negative effects on both physical and chemical indicators of water quality (Kauffman and Krueger 1984). Reduction in the diversity and productivity of the herbaceous vegetation layer can change the velocity and erosive energy of the stream flow, while losses of the woody overstorey have large effects on water temperature. Both the overstorey and understorey vegetation layers have important effects on the rates and kinds of aquatic

processes that occur in a stream (Kauffman and Krueger 1984), and the diversity and productivity of invertebrates and fishes are profoundly influenced by the diversity of the streamside vegetation.

6.1.7.8 Biotic linkages and species interactions

Human impact on biodiversity. Invasions in grasslands are common and in some cases have been associated with changes in grazing regime. Examples of grasslands that have been invaded by exotic species are the California grasslands and the intermontane west of North America, the *pampas* in South America, and the savannahs in tropical South America (Sala *et al.* 1986; D'Antonio and Vitousek 1992).

Ecosystem consequences of the impacts. Invasions in grasslands have usually occurred in association with an increase in grazing intensity and/or a change in dominant grazer. Vulnerability to invasions associated with grazing appears to be related to moisture availability and the grazing history in evolutionary time (Milchunas *et al.* 1988). Grasslands that evolved under light grazing conditions and under mesic conditions are more vulnerable to invasions than those that evolved under heavy grazing in xeric environments. Semi-arid grasslands of the northwest USA and southwest Canada have a short evolutionary grazing history, and before the introduction of cattle they were dominated by perennial tussock grasses (Tisdale 1947; Daubenmire 1970). The inability of these grasses to cope with heavy grazing resulted in the invasion and dominance of many areas by Eurasian weeds (Daubenmire 1940, 1970; Ellison 1960; Mack 1981; Mack and Thompson 1982). Invasions often disrupt competitive interactions (D'Antonio and Vitousek 1992) which result in changes in species composition with the ecosystem effects described above.

6.1.7.9 Microbial activities

Human impact on biodiversity. See discussion of decomposition and soil structure above.

Ecosystem consequences of the impacts. The effect of changes in plant species diversity on microbial activity as a result of changes in litter quality and quantity are described in the decomposition section above.

6.1.7.10 Summary and relevance to human activities

On a world-wide basis the response of grasslands to the major human use – domestic livestock grazing – has been variable (Milchunas and Lauenroth 1993). In some areas where the native vegetation is well adapted as a result of evolution, changes in biodiversity have been very small (Milchunas *et al.* 1988). In other areas changes have been very large. In some cases and especially in tropical and subtropical grasslands, the large changes have involved a shift from a grass-dominated vegetation to one dominated

by woody plants (Walker *et al.* 1981; vanVegten 1983; Archer 1989). In other cases the large changes have involved invasions of exotic plants which have profoundly altered the ecosystems. Conversion of grasslands to croplands or seeded pastures has also had a major influence on biodiversity and ecosystem functioning. In many cases these converted grasslands have become net sources of carbon and nutrients accelerating global change. These major transformations of grasslands and their effects on biodiversity modify the water, carbon and nutrient cycles to an extent that significantly contributes to altering the Earth's life support system.

6.1.8 Mediterranean-type ecosystems

6.1.8.1 Introduction

Mediterranean-type ecosystems share a climate of cool wet winters and a distinct summer drought, and are found in the Mediterranean Basin, California, Chile, the Cape Province of South Africa and southwestern and southern Australia. Estimates of biome cover vary depending on the climatic classification used, but are approximately as follows, given as 10⁶ km² (estimates of numbers of plant species in each region are given in parentheses where available): Mediterranean Basin 1.87 (c. 25 000), California 0.32 (5050), Chile 0.14 (c. 2100), Cape Province 0.09 (c. 8550), Southwestern Australia 0.31 (c. 8000) (Quézel 1981; Cowling *et al.* 1992; Fuentes *et al.* 1995; Hobbs *et al.* 1995; Keeley and Swift 1995). The last four regions are listed as 'hot spots' for species diversity by WCMC (1992), although parts of the Mediterranean Basin also possess high plant diversities, as estimated on a species per km² basis (Davis *et al.* 1986; Valdés *et al.* 1987; Moreno Saiz

and Sainz Ollero 1993). The five regions have markedly different biogeographic characteristics, histories and current patterns of human habitation and use, and markedly different patterns of biodiversity. These differences are most clearly obvious between the Mediterranean region, which has a long history of human habitation, and some of the areas more recently settled by Europeans, such as Australia. Mediterranean-type ecosystems consist of a variety of vegetation types, including forest, woodland, shrubland and grassland. A feature of many of the vegetation types is their sclerophyllous nature, and high levels of secondary compounds such as terpenes. Floristic diversity and degree of endemism are high in most Mediterranean areas, and shrublands in Australia and South Africa are particularly noted for their high floristic diversity.

Human impacts on biodiversity vary between regions, and include both positive and negative components. In the Mediterranean Basin, where human activities have modified the landscape for thousands of years, current levels of biodiversity are in part maintained by continued human influence. Where traditional human activities cease, plant and animal diversity can be reduced (González Bernáldez 1991; Naveh 1994) and susceptibility to disturbances, especially fire, can be increased (Moreno 1989). This in turn can promote landscape homogenization, with resultant negative effects on biodiversity (Faraco *et al.* 1993; Pérez *et al.* in press). Landscape homogenization can also result from the abandonment of agricultural/pastoral land (Fernández-Alés *et al.* 1992). Human activities have also played an important role in determining the distribution of vegetation and ecosystems in Chile, and may be important in the retention of components of the biodiversity within these ecosystems (Fuentes and Muñoz 1994; Fuentes *et al.* 1995).

In South Africa and Australia, and in California, human impacts are largely negative. These include reductions in population size and/or distribution of sensitive species which have occurred as a result of land-use changes and fragmentation (Saunders 1989, 1993; Hopper *et al.* 1990; Cowling and Bond 1992; Hopper 1992). Reduced age structure diversity of dominant species results from altered disturbance regimes (Yates *et al.* 1994); genetic diversity is reduced through habitat loss (Rebelo 1992), and loss of species diversity is caused by introduced predators, herbivores, plants and diseases (Mooney *et al.* 1986; di Castri *et al.* 1990; Groves and di Castri 1991; Scougall *et al.* 1993; Wills 1993).

Reduced structural complexity can occur because of management practices such as post-fire re-seeding (Barro and Conrad 1987) or deforestation, but this is countered in some cases by local increases in complexity through reforestation (Blondel 1976). Human activities can maintain structural diversity where vegetation patterns are

largely a result of past activities, especially in the Mediterranean Basin and Chile. Ecosystem and landscape fragmentation and simplification result from agriculture, forestry and urbanization, and changed disturbance regimes. This includes the addition of new disturbances, modification of natural regimes, and the discontinuation of traditional human management (Le Houérou 1990; Van Wilgen *et al.* 1992; Aronson *et al.* 1993; Hobbs 1993; Hobbs *et al.* 1993; Keeley 1993). The introduction of exotic species and altered disturbance regimes affect biodiversity at all levels. The likely magnitude of impacts is uncertain and varies between regions.

6.1.8.2 Productive capacity, biomass and decomposition

Human impacts on biodiversity. Changes in productive capacity and biomass result from type conversions, the invasion of exotic species, grazing by introduced herbivores, spread of pathogens and changed disturbance/management regimes (references in Introduction)

Ecosystem consequences of impacts. Impacts on biodiversity can cause a net decline in biomass and productive capacity in areas subject to transformation by agriculture (with a switch toward human-orientated productivity), urbanization or grazing (Scougall *et al.* 1993; Keeley 1993). Reduced diversity may lead to reduced resilience to episodic disturbances such as fire, flood and drought (Atkins and Hobbs 1995). Effects on resilience will become apparent only over long time-frames. Localized increase in productive capacity can occur where invasion by N-fixers occurs (Macdonald and Richardson 1986; Stock and Allsop 1992). This also occurs after fire or abandonment in the Mediterranean Basin, where fast-growing native legumes invade (Faraco *et al.* 1993; Pérez *et al.*, 1995).

6.1.8.3 Soil structure and nutrients

Human impacts on biodiversity. Changes result from type conversions, agricultural development and loss of native plant cover, changes in grazing management, and changed fire regimes (references in Introduction)

Ecosystem consequences of impacts. Reduced uptake and increased efflux can occur where there is a loss of functional groups with specialized uptake mechanisms (Hobbs 1993b). Reduced soil aeration and loss of macropore structure result from the loss of soil macrofauna (Hobbs *et al.* 1995). These are certain, widespread impacts. Nitrogen fixation can increase or decrease following addition or deletion of N-fixers (Stock and Allsop 1992), with concomitant changes in ecosystem response to disturbance. The direction of change is dependent on which species are added or lost. Changed fire cycles and intensities lead to changes in soil chemical and structural properties, erodability and nutrient losses (Scott and van Wyk 1990; Marion *et al.* 1991; Giovannini 1994; Riggan *et al.* 1994). Fire intensity can profoundly alter post-fire

ecosystem functioning, both directly and indirectly (Moreno and Oechel 1994). These are likely to be localized effects.

6.1.8.4 Water distribution, balance and quality

Human impacts on biodiversity. Changes result from agricultural development and loss of native plant cover, loss of riparian and wetland vegetation, and reduced landscape heterogeneity through fragmentation, land abandonment and afforestation (references in Introduction).

Ecosystem consequences of impacts. Reduced structural and landscape diversity leads to reduced buffering and greater peak flows. Reduced diversity of groups with specialized water redistribution and uptake mechanisms leads to reduced internal redistribution, lower water use, greater vertical and horizontal water movement and increased salinization and erosion (Nulsen *et al.* 1986; Scott and van Wyk 1992; McFarlane *et al.* 1992, 1993). Reduced species and landscape diversity also lead to reduced resilience to episodic high rainfall events, for the same reasons. These are certain, widespread effects, which occur over time scales of years to decades. The use of natural water containing non-pathogenic levels of *Phytophthora cinammomi* for irrigation leads to pathogenic outbreaks in transformed systems (Von Broemsen 1984).

6.1.8.5 Atmospheric properties

Human impacts on biodiversity. Of potential importance is the large-scale removal of complex perennial vegetation and its replacement by agriculture (Hobbs *et al.* 1993).

Ecosystem consequences of impacts. Regional changes in albedo, evaporation, cloud formation and rainfall distribution may be caused by changes from complex perennial vegetation to annual crop and pasture land (Smith *et al.* 1992). Changes are uncertain, but could be widespread.

6.1.8.6 Landscape and waterscape structure

Human impacts on biodiversity. Fragmentation, urbanization, type conversion, deforestation and reforestation, and changes in disturbance regimes (references in Introduction) are particularly important.

Ecosystem consequences of impacts. Impacts result in reduced landscape diversity and connectivity and increased probability of landscape degradation (Fernández Alés *et al.* 1992; Hobbs *et al.* 1993; Keeley 1993). Reduced landscape and structural diversity around water bodies leads to changes in chemical, physical and biotic characteristics (e.g. a change from freshwater to saline: Froend *et al.* 1987; Bell and Froend 1990; Froend and McComb 1991). There is also a higher probability of irreversible system change following episodic storm events. Changes could be widespread.

6.1.8.7 Biotic linkages and species interactions

Human impacts on biodiversity. Species introductions have potentially large impacts on diversity at all levels

(Mooney *et al.* 1986; di Castri *et al.* 1990; Groves and di Castri 1991) and species deletions can result from changes in landscape structure caused by habitat modification, homogenization, fragmentation and changes in utilization patterns (references in Introduction).

Ecosystem consequences of impacts. Consequences include the disruption of obligatory mutualisms involving for example pollination or dispersal and the breakdown of complex systems of predator–prey and plant–herbivore interactions (Fuentes and Etchegaray 1983; Bond and Slingsby 1984; Bond and Stock 1989; Jaksic *et al.* 1992; Main 1992; Norton *et al.* 1994; Fuentes *et al.* 1995). Such changes may have potential follow-on effects on productive capacity, nutrient uptake and retention, and ecosystem response to disturbance, although the exact nature of these follow-on effects will be difficult to predict. Introduced plant species have been shown to have a positive effect on honey production in Chile, which is dependent on the presence of an array of species with different flowering times (Fuentes *et al.* 1995). Follow-on effects are most likely where the species lost are ‘keystones’ or have no functional equivalents.

6.1.8.8 Microbial activities

Human impacts on biodiversity: New suites of micro-organisms, including pathogens, soil micro-organisms and nitrogen-fixing and mycorrhizal symbionts have been introduced into areas where they were previously absent (Stock and Allsopp 1992). Human modification of ecosystems may also induce pathogenic outbreaks of organisms previously present at non-pathogenic levels (Von Broembsen 1984). Alterations to soil and litter characteristics resulting from agriculture and ecosystem modification will lead to changes in microbial activities, although it is not known exactly how microbial diversity is affected (e.g. Brandenburg and Sparling 1990).

Ecosystem consequences of impacts. Introduced pathogens dramatically alter ecosystem structure and functioning, and can differentially affect specific plant functional groups (Wills 1993; Hobbs 1993a). Loss of N-fixers through altered disturbance regimes, or their addition through introduction with invasive plants may alter nutrient cycling (Hobbs 1992; Stock and Allsopp 1992). Pathogens that cause the death of above-ground plant parts may also alter fuel properties and hence affect fire behaviour and intensity (Riggan *et al.* 1994). Changes in microbial populations also lead to changes in soil respiration (Brandenburg and Sparling 1994). The extent and importance of these changes is largely unknown.

6.1.8.9 Summary and relevance to human activities

Mediterranean-type ecosystems are generally made up of a mosaic of different vegetation types, and the five Mediterranean regions, while resembling each other in

some ways, differ greatly in their levels of diversity and degree of modification. This heterogeneity both between and within regions makes generalizations difficult. Mediterranean regions are generally heavily populated and modified, and the major impacts on biodiversity arise from this modification, particularly at the landscape scale. In the Mediterranean Basin, the continuation of traditional human activities maintains landscape heterogeneity and has a positive influence on biodiversity, while in Australia, recent human activities have had the opposite effect of reducing heterogeneity and negatively influencing biodiversity. The three other regions fall between these two extremes.

The likely consequences of changes in biodiversity are often unclear. In systems that are very species-rich, such as the South African *fynbos* or the Australian *kwongan*, the ecosystem effects of the loss of particular species may be minimal in the short term, although the longer term impacts on resilience to change and disturbance may be more important. On the other hand, reductions in ecosystem and landscape diversity have already had profound impacts in terms of altered hydrology and reduced agricultural production.

6.1.9 Coastal systems

6.1.9.1 Introduction

We use the term ‘coastal systems’ to mean the general marine region extending from the upper tidal limits out across the continental shelf, slope and rise (Brink 1993). This definition includes rocky shores, sandy beaches, kelp forests, subtidal benthos and the water column over the shelf, slope and rise. ‘Coastal systems’ are generally considered to encompass the Exclusive Economic Zones of nations (Highet 1992), a strip approximately 200 nautical miles wide along the 440 000 km long outlines of the

continents (Ryther 1969; Highet 1992; Goldberg 1993). This simple geographic definition is used for convenience. In reality, 'coastal systems' often represent the margins of larger ecosystems (Sherman *et al.* 1990), and they vary considerably depending on atmospheric, oceanographic, historical and geological factors. For example, island coastal systems often have much higher endemism than continental coastal systems (Castilla 1988). This review focuses on the nearshore benthic communities whose biological dynamics are better known than those of pelagic or deep sea communities. Estuaries, mangroves and coral reefs are covered elsewhere in this Section.

The importance of coastal systems to humanity is high: most of the world's people live within 80 km of the coast (Sobel 1993). Both land- and ocean-based activities are concentrated at the coastal margins: tourism, recreation, fishing, mariculture, domestic and industrial waste disposal, military activities, transportation, mining and energy industries (Goldberg 1993). Many kelp forests and rocky intertidal shores are among the most productive of any ecosystem in the world (Valiela 1984; Leigh *et al.* 1987; Highsmith and Coyle 1990). Coastal fisheries are the richest in the world, with more than 75% of the world's fish catch coming from coastal waters (FAO 1991; Brink 1993). In addition to the commercial importance of coastal fisheries, many people in developing countries obtain a significant amount of their nutrition from the consumption of local seaweeds, shellfish and fish (Tseng 1984; Bustamante and Castilla 1987; Durán *et al.* 1987; Santelices 1989; FAO 1991; Norse 1993). The aesthetic beauty of coastal shores, though difficult to evaluate in economic terms, is nonetheless real and invaluable to many.

Coastal and other marine systems differ from terrestrial systems in several important ways, both with respect to patterns of diversity and with respect to the functional implications of those patterns. High diversity is found not only at the species level as in terrestrial systems (where insects constitute the vast majority of animal species), but also at higher taxonomic levels. In general, marine systems have a much greater diversity of types of organisms and types of body plans than do terrestrial systems. For example, of the 33 extant phyla of animals (Margulis and Schwartz 1988), 32 occur in the sea, 15 are exclusively marine, and five are nearly so (see Section 3.2; Norse 1993). Most of these phyla are abundant in coastal systems (Ray 1991; Ray and Grassle 1991).

One consequence of the high level of diversity is that functional groups (see Section 5.2.2) often include species that are physiologically and genetically more distinct from one another than is the case within a comparable assemblage on land. One possible consequence of the greater differences among members of a functional group is a greater probability that the members will respond

differently to environmental changes. In other words, the greater the taxonomic diversity within a functional group, the greater the genetic and physiological base for adaptation to change. It is possible that this higher level of diversity confers on the marine world a greater potential for ecosystem resilience to change (see Section 5.2.2).

Primary producers in coastal systems are particularly diverse in many important ways. They range in size from microscopic plankton to giant kelps up to 60 m long. Most seaweeds are anchored to the bottom, but others, like the phytoplankton suspended in the water column, are transported in and out of the anchored communities. One result of this fluid transport is that carbon that is fixed in one place may be consumed or decomposed many kilometres away. The generally smaller size and faster growth rates of primary producers in the oceans is one reason why changes occurring over very large spatial scales (thousands of kilometres) can take place over much shorter temporal scales (weeks) compared to equivalent changes on land (Steele 1985). Primary producers in coastal systems are taxonomically diverse, and photosynthetic bacteria and protists play a much more prominent role than these groups do on land.

Biogeographic diversity patterns are well known for many marine taxa. Although some taxa (e.g. molluscs, fishes) exhibit the highest species diversity at lower latitudes, others (seaweeds) are most diverse at mid latitudes (Gaines and Lubchenco 1982; Bolton 1994), still others (marine mammals and bryozoa) are most diverse at higher latitudes, and many other taxa show no latitudinal cline at all (Clarke 1992). In temperate regions, the eastern margins of ocean basins tend to be more diverse than the western margins. Large inter-oceanic differences in diversity occur, and reflect, in part, geological and historical phenomena (see Section 3.2). The coastal biota of the temperate North Atlantic, for example, is less diverse than that of the North Pacific; and the macrophyte flora of temperate South America is depauperate compared with the temperate North Pacific or temperate Australasia.

6.1.9.2 Major human-induced impacts on and threats to biodiversity

Diversity of coastal systems is affected directly and indirectly by numerous human activities (Aronson 1990; Folke *et al.* 1991; Hammer *et al.* 1993; Norse 1993; Barbier *et al.* 1994; Perrings *et al.* 1994; National Research Council 1995). Threats include over-exploitation of fishes, invertebrates and seaweeds (for fishery and non-fishery uses); coastal aquaculture; physical alteration of the habitat (by trampling, trawling, dredging, drilling, dynamiting, building and dumping); noise pollution; thermal pollution; and chemical pollution from both toxins and nutrients. Long-term effects of oil spills are generally not well known, but some impacts have been found to be substantial

(Keller and Jackson 1993a, b). Biological invasions are a serious threat to biodiversity, especially in bays, estuaries and inland seas (Ben-Tuvia 1973; Ben-Yami and Glaser 1974; Dromgoole and Foster 1983; Spanier and Galil 1991; Carlton and Hodder 1995), and the transportation of potential invaders in the ballast water of ships has only recently been recognized as a serious concern (Carlton and Geller 1993; McCarthy and Khambaty 1994). Numerous activities occurring on land also have strong impacts on coastal systems: for example, logging, livestock grazing, agricultural practices, industrial activities, residential and resort development and damming vary the load of sediment, pesticides, sewage, industrial pollutants and other wastes delivered to coastal waters. Although global-scale threats such as climate change and increases in ultra violet-B radiation have strong potential to affect coastal regions (Smith *et al.* 1992; Castilla *et al.* 1993; Lubchenco *et al.* 1993; Peterson *et al.* 1993; Barry *et al.* 1995; Roemmich and McGowan 1995a, b), the threats to diversity from land-use practices and overfishing are real, serious and more immediate (Paine 1993; Perrings *et al.* 1994; National Research Council 1995). Many areas are already severely degraded. Moreover, the rates, spatial extent and types of perturbations are increasing alarmingly.

Documentation of the effects of these threats is severely hampered by several factors which, though applicable to many terrestrial systems, are often more chronic in marine systems (Grassle *et al.* 1991): they include (1) lack of long-term, basic baseline information about the distribution and abundance of biota and how the patterns change through time (Wood *et al.* 1993; but see Barry *et al.* 1995 and Roemmich and McGowan 1995a, b for exceptions); (2) inadequate basic systematic information and a paucity of trained taxonomists (Andersen 1992; Wood and Leatham 1992; Knowlton 1993; Knowlton and Jackson 1994; National Research Council 1995); (3) lack of documentation of extinctions (Carlton 1993); (4) difficulty in adequately surveying and sampling benthic and pelagic systems; (5) slow expression of the consequences, which often take years or decades to occur, and thus appear 'invisible' to humans (Magnuson 1990); (6) long-distance transport of chemicals (Bacon *et al.* 1992; Tatsukawa *et al.* 1994), organisms and phenomena. Coastal systems are strongly affected by processes occurring both in the immediate vicinity and far away, not only via air–water interactions but also through long-distance transportation within the aquatic medium. Spatial scale, transport and dispersal events are of particular importance to the dynamics of coastal systems (Gaines *et al.* 1985; Roughgarden *et al.* 1985; Grassle *et al.* 1991; Steele 1991; Levin 1992) and to the evolution of species within these systems (Palumbi 1992; Steinberg *et al.* 1995).

Despite these limitations to adequate documentation of impacts, many effects are all too obvious. The extinction of

numerous wild salmon runs and the ongoing decline of many of the remaining runs in the Pacific Northwest of the United States; eutrophication in Chesapeake Bay and Buzzards Bay in the eastern USA; effects of sewage sludge dumping off New Jersey, and the massive decline of most major fisheries, provide ample evidence of adverse impacts. Human exclusion experiments along the coast of Chile document previously unknown but dramatic direct impacts of people on the shore (Moreno *et al.* 1984; Castilla and Durán 1985; Durán *et al.* 1987; Durán and Castilla 1989; Castilla *et al.* 1993, 1994). Comparable changes may be occurring elsewhere (Dethier *et al.* 1989; Hawkes 1992; Addressi 1994).

6.1.9.3 Productive capacity, biomass, decomposition and nutrient cycling

Human impacts on biodiversity. Over-exploitation of coastal fisheries world-wide represents one of the most serious but least well documented threats to nearshore biodiversity. Despite the fact that overfishing of many commercially important fish and shellfish stocks has resulted in the demise of numerous fisheries throughout the world, there is often little specific information about the overall consequences to genetic, species or ecosystem diversity in most of the affected systems. The largest impacts may well be caused by indirect effects, as initial declines in target species in turn affect other species.

The effects of over-exploitation of a few species are known or can be inferred, especially where ecological relationships with the species' predators, symbionts, competitors or prey are known (Barkai and MacQuaid 1988; Paine 1993). The over-exploitation of sea otters along the northeastern rim of the Pacific Ocean, for example, has been well documented. Comparison of Aleutian Islands with and without otters suggests that the removal of this keystone predator in Alaska results in profound changes in the biodiversity of the rest of the kelp forest community (Box 6.1-1); Estes and Palmisano 1974; Estes *et al.* 1978; Duggins *et al.* 1989). Other changes in diversity resulting from overfishing have been described for Northwest Atlantic continental shelf systems (Sherman 1990), Haiti, the US Virgin Islands (Hay 1984), Hainan Island, China (Hutchings and Wu 1987) and the Baltic Sea (Hammer *et al.* 1993).

Ecosystem consequences of impacts. Little information is available with which to evaluate comprehensively the consequences of changes in diversity on production biomass, decomposition or nutrient cycling. We know of no studies evaluating the consequences of changes in number of species *per se*. However, there is evidence that changes in abundance of certain species can have profound impacts on these processes. For example, in the sea otter—sea urchin—kelp interaction (Box 6.1-1), the deletion of a single species (the otter) resulted in dramatic changes in biomass and probably also primary and secondary

Box 6.1-1: Sea otters: keystone predators in Alaskan kelp forests.

Sea otters in Alaska demonstrate the strong influence that a single species can have on an entire community. Otters play a pivotal role in maintaining kelp forests by eating and controlling sea urchins which consume kelps. In the absence of otters, urchins increase in size and numbers and overgraze the kelps. A lush kelp forest is thus converted to an 'urchin barren', a community composed primarily of a pavement of encrusting coralline algae and urchins (Estes and Palmisano 1974; Simenstad *et al.* 1978; Duggins *et al.* 1989). Urchin barrens are devoid of kelps and other large seaweeds, and lack the diverse assemblage of macroscopic benthic and pelagic invertebrates and fishes, and marine mammals associated with kelp forests. The otter is thus a 'keystone' species because it exerts a disproportionately large influence on the entire community (see Box 5.2-1).

Conversion of a kelp forest to an urchin barren results in the loss of important ecosystem services. In addition to providing a habitat for resident species, kelp forests may also function as important nursery areas for many fish (Carr 1994) and may modify larval transport to adjacent shores (Gaines *et al.* 1985). They also provide dissolved and particulate organic matter that is consumed locally and by organisms such as deposit- and filter-feeding mussels, clams and barnacles in adjacent intertidal and subtidal communities (Duggins *et al.* 1989). Moreover, kelp forests often protect coastal shorelines from the full force of waves, especially during winter storms. In this case, the absence of a keystone species results in the conversion of a community from a lush forest to a depauperate plain with attendant loss of habitat, primary and secondary production, export to nearby systems and buffering capacity to nearshore areas.

production, nutrient cycling, decomposition, and export of organic matter to nearby systems (Estes and Palmisano 1974; Simenstad *et al.* 1978; Duggins *et al.* 1989).

Alterations in the relative abundance of phytoplankton or macrophytes resulting from climate change could have important cascading consequences for the structure and functioning of the rest of the coastal systems (Peterson *et al.* 1993), but the specific consequences to primary production, biomass, decomposition and nutrient cycling cannot be predicted with confidence.

Climate change has been predicted to result in warmer water, sea level rise (Houghton *et al.* 1990, 1992) and alterations in coastal upwelling patterns (Bakun 1990). Each of these would be likely to have effects on biodiversity, though the direct and indirect changes are difficult to predict (Castilla *et al.* 1993; Lubchenco *et al.* 1993; Paine 1993; Peterson *et al.* 1993). Barry *et al.* (1995) report shifts in temperatures and in intertidal plants and animals over a 50-year time span in Monterey Bay, California, USA, which may be due to global warming. Different taxa of macrophytes as well as phytoplankton vary considerably in their responses to changes in temperature and their ability to take up and store nutrients (Wheeler 1983; Fujita 1985). Changes in the frequency, duration or intensity of coastal upwelling would be expected to alter the relative abundances of the major taxa of macrophytes and phytoplankton as well as affect the overall levels of productivity (Menge *et al.* 1995; Roemmich and McGowan 1995a, b).

6.1.9.4 Sediment structure

Human impacts on biodiversity. Dredging, trawling, anchoring, trampling, raking and digging have wide-

ranging but sporadically documented consequences for marine biota. These activities disrupt sediment structure, destroy burrows, bury or clog organisms and suspend particles, and modify wave and tidal energy, all of which may affect patterns of diversity in soft-sediment environments (McLachlan *et al.* 1993). One short-term effect of sediment resuspension should be increased respiration and mineralization of sediment organic matter and a consequent increase in inorganic nutrients into the water column. Increase in nuisance phytoplankton blooms would be expected to follow. Other expected consequences include mobilization of toxic metals and inorganics into the water column and a disruption of anaerobic microzones and thus biogeochemical cycles.

The use of new, economically more efficient techniques for harvesting shellfish can sometimes have negative consequences on the target commercial species and the rest of the community compared with traditional hand-gathering techniques (Defeo 1989, 1993). Contamination of freshwater effluents by human activities (e.g. through the use of chemicals and increased nutrients from agriculture) can affect the composition of these communities and potentially reduce species diversity above and beyond the effect produced by the reduction in salinity (Defeo *et al.* 1990; Defeo 1993). Taxa vary widely in the extent to which they themselves modify the structure of the sediments and thus alteration of sediment structure may result in further modifications through trophic and non-trophic interactions among species. Intra- and interspecific biological interactions are poorly understood in these systems.

Ecosystem consequences of impacts. The ecosystem consequences of these disruptive activities are largely

Figure 6.1-4: Trophic linkages between nuisance phytoplankton blooms and species illustrating some direct and vectored routes through which toxins, inimical species and anoxia affect the depicted compartments and may cause recruitment failure and/or mortality (after: Smayda 1992).

unknown. The experimental exclusion of humans to create a *de facto* closing of the fishery of the yellow clam *Mesodesma mactroides* from a sandy beach on the coast of Uruguay illustrates, however, that these activities can have far-reaching consequences. The yellow clam is an important artisanal fishery in Uruguay, and many fishing communities are devoted to its extraction (Defeo 1989). The experimental manipulation of the fishery led to important changes in overall abundance and in the kinds of processes regulating the dynamics of the populations of not only *M. mactroides* but also the coexisting wedge clam, *Donax hanleyanus*, which is not exploited by humans (Defeo 1993; Defeo and DeAlava 1995). Changes in the abundance of other non-exploited species were also observed following the ‘exclusion’ of humans.

6.1.9.5 Water movement and quality

Human impacts on biodiversity. Nutrients in shallow coastal systems are taken up directly from the aquatic medium, and nutrient availability is heavily affected by sewage discharge, freshwater runoff, dumping of industrial wastes, and atmospheric deposition of toxics and nutrients. In 1982, anthropogenic inputs of nutrients to coastal waters were estimated to equal or exceed natural inputs (Meybeck

1982). The UN’s Group of Experts on the Scientific Aspects of Marine Pollution (GESAMP 1991) has ‘identified nutrients as the most damaging class of pollutants in the marine realm’ (Norse 1993). Nutrient enrichment of coastal waters is generally characterized by increases in primary production, shifts in the relative abundance of phytoplankton species, dense plankton blooms and nuisance macro-algal blooms (GESAMP 1991; Norse 1993). One specific mechanism of these shifts appears to be alteration in the Si:N and Si:P ratios, which favour non-diatom blooms (Smayda 1992). Explosive increases in certain taxa such as various dinoflagellates produce ‘redtides’. The diversity of organisms producing toxic phytoplankton blooms has increased during the last few decades (Wood *et al.* 1993), and the frequency, extent and intensity of toxic phytoplankton blooms is increasing (Dundas *et al.* 1989; Smayda 1990; Hallegraeff 1993). Moreover, certain blooming species are apparently spreading globally, perhaps aided by transport in the ballast water of ships (Hallegraeff and Bolch 1991). Smayda (1990) terms this ‘a global epidemic’ with far-reaching consequences.

Ecosystem consequences of impacts. Coastal eutrophication has dramatic effects on water quality,

aquaculture, fisheries, human health and ecosystem structure and functioning. The well-known effects of coastal eutrophication include toxic algal blooms, anoxia, fish kills, shifts to a decomposition food web, and loss of water quality (Fenchel *et al.* 1990; Turner and Rabalais 1991). Red-tide or other algal blooms can result in human health hazards such as paralytic shellfish poisoning or aquacultural die-offs (Richardson 1989). Toxins produced by red-tide blooms have recently been shown to result in a wide variety of other ecosystem effects, ranging from reduced fecundity and recruitment and increased mortality of fishes (Smayda 1992) to marine mammal die-offs (Geraci *et al.* 1989) (Figure 6.1-4). Hence, differential responses of phytoplankton taxa to nutrient shifts can result in substantial alteration of the relative abundance of phytoplankton with far-reaching consequences involving not only water quality but also other ecosystem properties as well. Changes in the relative abundance of phytoplankton taxa are also influenced by shifts in the relative abundance of zooplankton and higher trophic level taxa.

6.1.9.6 Feedbacks to atmospheric properties

Human impacts on biodiversity. A wide variety of bacteria, phytoplankton and macrophytes produce gases that have been suggested to be of potential importance to the radiative balance of the Earth's atmosphere. Chemically important marine biogases include species of carbon (CO_2 , CO , CH_4), sulphur (DMS), nitrogen (N_2O , NH_3), and halogens (CH_3I , CH_3Cl , and CH_3Br) (Wolfe *et al.* 1991). Some of these gases are also produced by terrestrial biota. However, the marine environment is thought to be the main source of dimethylsulphide (DMS) and carbonylsulphide (COS), two trace constituents of the atmosphere which have important effects on the global atmospheric and climatic balance (Charlson *et al.* 1987; see also 6.2.4). The production of atmospherically active gases is not uniformly distributed among species within a given habitat. A few species produce a disproportionate fraction of the most active atmospheric constituents (e.g. bacterial catabolism of certain phytoplankton species produces a large fraction of all the atmospheric DMS). Factors affecting the relative abundance of these species have the potential to exert large effects on the atmosphere and consequently the global climate. Pollutants, eutrophication of coastal waters, sedimentation, and depletion of atmospheric ozone with the consequence of increasing UV-B radiation (Karentz 1991; Helbling *et al.* 1992; Smith *et al.* 1992) can all alter the diversity and abundance of these producers and thus have the potential to alter global climate.

Ecosystem consequences of impacts. Emission of DMS from the open ocean and its effect in the formation of cloud condensation nuclei (CCN) has been hypothesized to be a

major regulatory factor of the global climate. Production of DMS varies dramatically depending on species composition (Keller *et al.* 1989). It is also known that blooms of calcifying coccolithophorids found in coastal waters have global significance in the CO_2 and DMS cycles (Holligan *et al.* 1983; Matrai and Keller 1993; Brown and Yoder 1994). Although factors regulating both species composition and the outbreak of blooms are not clearly understood in these systems, alteration of these regulatory factors (e.g. the relative availability of nutrients) by human activities can have potential global consequences.

The coastal marine environment is the main biogenic source of COS, which is thought to be the major source of sulphur in the stratosphere. After oxidation, these constituents play a major role in the global radiation budget and thus climate, by scattering sunlight back to space and interfering with stratospheric ozone (Lazrus and Gandrun 1977; Hofman 1990). The general degradation of coastal environments can affect the global levels of CS_2 , changing the atmospheric composition and in turn affecting the rest of the biota.

6.1.9.7 Landscape and waterscape structure

Human impacts on biodiversity. Coastal systems are characterized by steep physical gradients in desiccation, wave action, water movement, depth, light attenuation, mixing, temperature, particle size, particle movement, salinity and substrate type. One consequence of these steep gradients is a high landscape diversity, with rocky shores closely juxtaposed with sandy beaches, kelp forests, estuaries or other habitats. The linkage of these different communities by water flowing and organisms moving within and among them provides for substantial interchange. Human activities such as over-exploitation of resources, physical alteration of the habitat, pollution, introduction of alien species and climate change are already affecting genetic, species and ecosystem diversity and hence modifying landscape structure.

Ecosystem consequences of impacts. Most landscape-level alterations resulting from changes in biodiversity have not been well documented. The potential for these changes is illustrated in the greater Everglades ecosystem in Florida, USA. Massive alteration of natural hydrologic patterns for flood control and development throughout the entire Everglades region appears to be one of the primary triggers of the ecological collapse of Florida Bay (Butler *et al.* 1994). The enormous anthropogenic flows of flood waters into coastal waters to the east and west of Lake Okeechobee have decimated hard-bottom communities.

Two smaller-scale examples provide more information about possible roles of biodiversity in mediating landscape-level changes. The absence of sea otters from certain Aleutian islands (Box 6.1-1), and the creation of marine

protected areas in intertidal sites in Chile, illustrate how changes in diversity mediated through deletions of a top predator have resulted in drastic alteration of the ecosystem and landscape structure. Conversion of a kelp forest to an urchin barren modifies water movement patterns, delivery of dissolved and particulate organic matter to adjacent intertidal beaches and intertidal and subtidal rocky shores, protection of juvenile fishes and hence recruitment into pelagic communities. In Chile, humans remove gastropods (Oliva and Castilla 1986; Durán *et al.* 1987), seaweeds (Castilla and Bustamante 1989) and fishes, and because of the effects of each of these groups on other species in the community, the result is a transformation of the community.

6.1.9.8 Biotic linkages and species interactions

Human impacts on biodiversity. Overfishing, overcollecting, trampling, modification of the physical structure, pollution and species introductions are all substantial threats to coastal biodiversity. Influences range from 'bottom-up' effects wherein species at the base of the food web are affected first (e.g. eutrophication or harvesting of macrophytes) to 'middle-out' effects involving alterations in herbivores (e.g. harvesting of sea urchins or herbivorous fishes), to 'top-down' effects where top predators are directly affected (e.g. removals of otters, molluscs, sea stars, lobsters, sharks and other fishes). The relative importance of these regulatory effects may vary among communities and along environmental gradients (Sousa 1979; Menge 1992). None of these impacts is limited to the taxon, functional group or trophic level first affected; all of these effects reverberate throughout the rest of the ecosystem via biological interactions.

Ecosystem consequences of impacts. Biotic interactions and species linkages are particularly well known from nearshore coastal benthic communities where experimental manipulation of species has resulted in a mechanistic understanding of the links among species, including the importance of interaction strength, keystone species, and compensation among species within a functional group (reviewed in Paine 1980, 1992; Menge *et al.* 1994; Power *et al.* 1995; Power and Mills 1995). If keystone species are removed, for example, the entire ecosystem can be affected. Sea otters and sea-stars provide well-documented examples (Box 6.1-1). In contrast, some systems are characterized by the lack of a keystone species (Menge and Lubchenco 1981; Robles and Robb 1993). These systems provide an interesting comparison which is immediately relevant to the relationship between biodiversity and ecosystem functioning. Rocky intertidal shores on the Pacific coast of Panama have rich diversity within all trophic and functional groups (Lubchenco *et al.* 1984). Experiments demonstrate that the entire assemblage of

predators and herbivores has dramatic effects in maintaining the barren appearance of the shores. However, no single species or group of species has a demonstrable effect. Removal of species or functional group such as molluscan predators or molluscan herbivores or large fishes or small fishes and crabs has little effect on the community because other groups with overlapping functions compensate for the absence of the target group (Menge *et al.* 1986). High diversity within the functional groups of this community provides for continuation of the function in the absence of any individual constituents (Menge *et al.* 1986; Menge and Lubchenco 1981). This is a fundamentally different result from that obtained in Alaskan kelp communities or rocky intertidal shores off Washington and Oregon (Paine 1966, 1994; Menge *et al.* 1994) or tide pools in New England (Lubchenco 1978) where removal of a single keystone species totally changes the community. The Panama system is characterized by high functional overlap and thus the potential for compensation.

Even in communities such as rocky intertidal systems where the relationships between species diversity and community patterns and processes are among the best understood of any assemblage, relatively little is known about effects at the ecosystem level. The consequence of removal of keystone species to nutrient flows, rates of production or decomposition have not been measured.

6.1.9.9 Microbial activities

Human impacts on biodiversity. Several anthropogenic changes have had broad impacts on micro-organisms. Excess nutrient input from sewage, fertilizers and soil erosion can drastically change nutrient availability in many coastal systems (GESAMP 1991; Norse 1993). Increased UV irradiation from a thinning ozone layer probably has a detrimental effect on phytoplankton over vast areas (Hebling *et al.* 1992; Smith *et al.* 1992). Warming from climate change reduces available oxygen and probably favours some species over others (Epstein *et al.* 1993) or causes evolutionary change in organisms that experience these environmental impacts as a form of directional selection (Lynch *et al.* 1991; Lynch and Lande 1993). Both processes are likely to change the structure of microbial communities, with unpredictable impacts on ecosystem functioning.

The biodiversity of marine microorganisms has been greatly underestimated in the past. Only recently, through molecular methods, has the tremendous taxonomic diversity of these groups begun to be documented (Giovannoni *et al.* 1990; Fuhrman *et al.* 1993). Specific impacts on this diversity are thus poorly understood.

Ecosystem consequences of impacts. These broad impacts may have several consequences. Nutrient influx has created a variety of eutrophication problems in many

coastal regions (Richardson 1989; Turner and Rabalais 1994). For example, a cascade of disturbances, apparently caused by an increase in cyanobacterial blooms in Florida Bay, Florida, USA, has caused the widespread loss of sponge populations and a decline in lobster abundance (Butler *et al.* 1994). Outbreaks of human disease, such as cholera, have been linked to plankton reservoirs that have been enhanced by nutrient addition (Epstein *et al.* 1993). Further, anoxic conditions created by algal blooms have been implicated in significant mortality of fish stocks and benthic fauna in several regions (Tulkki 1965; Jorgensen 1980; Richardson 1989). Numerous unexplained mass mortalities or disease outbreaks remain enigmatic, though pathogens are often suspected of playing key roles, for example in urchins (Lessios *et al.* 1984; Lessios 1988), asteroids (Dungan *et al.* 1982), abalone (Steinbeck *et al.* 1992; Richards and Davis 1993), sea grasses (Rasmussen 1977) and marine mammals (Dietz *et al.* 1989). In most cases, neither the causes of the outbreaks nor the specific vectors are known.

Viruses, previously disregarded by marine microbiologists, are clearly important in regulating phytoplankton (Suttle *et al.* 1990) and bacterioplankton populations (Bergh *et al.* 1989; Bratbak *et al.* 1990; Proctor and Fuhrman 1990). As with symbiotic relations, virus–host interactions are highly species-specific and changes in diversity will change the dynamics of these interactions (Steward *et al.* 1992).

Loss of certain functional groups (see Section 5.2.2) such as methane oxidizers would have a dramatic effect on global biogeochemistry because these functional groups are taxonomically limited in scope.

Close coupling of temperature for maximum growth rate and average temperatures *in situ* have profound impacts on bacterial growth and the fate of carbon from phytoplankton in high latitude seas (Pomeroy and Deibel 1986; Pomeroy *et al.* 1991; Wiebe *et al.* 1992). Similar close correlation between *in situ* temperatures and optimum growth rate has been observed in other members of the microbial community from the Arctic (Choi and Peters 1992) and bacterial communities from temperate ecosystems (Shiah and Ducklow 1994), suggesting that the entire microbial food web of a given environment will be very sensitive to changes in average temperature, even if this involves a change of only a few degrees.

6.1.9.10 Summary and relevance to human activities

Coastal systems are among those most heavily affected by humans. They are also among the systems most vital to humans, and provide food, recreation, inspiration, transportation, waste disposal, and the buffering of coastlines from erosion. Threats to biodiversity in these systems are multiple and serious; they may also be synergistic. The full impact of the resulting changes to

diversity are not sufficiently known, but early indications suggest they may be profound. The effects of over-exploitation and pollution are increasingly obvious and serious but the full consequences of species introductions, physical habitat destruction, changes in UV-B radiation and climate change are yet to be documented.

6.1.10 Coral reefs

6.1.10.1 Introduction

The complex and diverse assemblage of organisms that constitutes the coral reef ecosystem covers over 600 000 km² (<30 m deep) of the tropical ocean. Over half this area is in the Indo-Western Pacific and about 15% is in the tropical Atlantic, the two centres of reef diversity (Smith 1978; Veron 1986; World Conservation Monitoring Centre 1992) (Figure 6.1-5). Modern coral reefs, representing approximately 6000 years of growth during the most recent period of sea-level rise, have an average gross carbonate production of 10 kg/m²/yr and average vertical growth rates of 3 mm/yr (Chave *et al.* 1972; Smith 1983). They are the oldest and largest biogenic structures in nature, holding detailed palaeoecological and climate records (Smith and Buddemeier 1992; Dunbar and Cole 1993). Coral reefs have more species per unit area than any other marine ecosystem but, with the exception of a few groups such as fishes and corals, most are poorly studied (Böhlke and Chaplin 1968; Springer 1982; Achituv and Dubinsky 1990; National Research Council 1995). Reefs have fewer species than tropical forests, with which they are often compared, but a much higher phyletic diversity (Ray and Grassle 1991; Briggs 1994). Disturbance appears to play a major role in the maintenance of species diversity in coral reefs,

(Connell 1978; Harmelin-Vivien and Bourlière 1989; Sale 1991a, b). However, the uncertain species-level taxonomy of even the best-known organisms makes it difficult to evaluate with confidence either the total number of species or the role of niche diversification among them (Knowlton and Jackson 1994). Many coral reef species rely for population replenishment on larvae released from ‘upstream’ reefs. This reliance may increase opportunities for genetic diversification compared to populations replenished from local stocks and/or by vegetative reproduction, which are also common among reef species (Benzie 1994). Day-to-day metabolic requirements are provided by a low steady supply of inorganic nutrients (D’Elia and Wiebe 1990). While reefs are characterized by the complexity of their biological relationships, it is their ability to construct massive calcium carbonate frameworks which sets them apart from all other ecosystems. The construction comes about through interactions of organisms, heuristically lumped into functional groups, including framework builders (corals), facilitators (symbiotic algae), and grazers (Figure 6.1-6). Studies of reef communities through geological time or across gradients of diversity indicate that different combinations of species may constitute a functional group (Jackson 1992, 1994a). However, changes in keystone species (single-species functional groups) can cause dramatic alterations in reef structure and functioning.

6.1.10.2 Threats to reefs

The principal direct human impacts that threaten reefs are nutrient loading, sedimentation and destruction from poor land-use practices, dredging and coral mining. Reefs hold a significant proportion of the world’s fishery resources, and they are very sensitive to overfishing, particularly the removal of large predators and herbivorous fishes (Salvat 1987; Wells 1988; Hatcher *et al.* 1989; Russ 1991). A key feature of human impact on reefs is the disturbance of biotic and abiotic factors which shift reef composition from framework builders (corals) to non-framework builders

(algae; Figure 6.1-6). While global climate change, including sea-level rise, increased seawater temperatures, and increased ultraviolet (UV-B) radiation, are a potential long-term threat to reefs, there is an immediate need to manage the impact of relentless coastal human population growth (D’Elia *et al.* 1991; Norse 1993).

6.1.10.3 Productive capacity, biomass and decomposition

Human impacts on biodiversity. Reef corals thrive in the low but steady input of nutrients from the oligotrophic ocean waters of the tropics. Extreme nutrient loading may disrupt the dynamic balance of corals and algae in favour of the benthic algae which can overgrow, shade and smother corals (Littler and Littler 1985). Suspended sediments and planktonic algal blooms may shade corals and result in over-dominance of benthic algae.

Ecosystem consequences of impacts. Coral reef productivity, respiration and calcification have been well studied, and ‘standards of functional performance’ have been suggested as indicators of ecosystem health (Odum and Odum 1955; Johannes *et al.* 1972; Kinsey 1991). In a healthy reef, the ratio of gross Productivity/Respiration = 1, indicating internal cycling. This P/R ratio can shift to >1 if there are excessive nutrients, additional production and export, or to <1 if there is increased respiration over production implying import of material (D’Elia and Wiebe 1990; Kinsey 1991). Excess nutrients stimulate algal growth and can inhibit calcification and reef bioconstruction, shifting the balance to bioerosion (Kinsey and Davies 1979; Hallock and Schlager 1986).

6.1.10.4 Sediment structure and nutrients

Human impacts on biodiversity. Increased sedimentation from poor land-use practices may change sediments from aerobic to anaerobic as organic material accumulates. Nutrients may then ‘bleed’ out of the sediments over time, stimulating benthic productivity and prolonging the impact long after corrective measures have been taken (Maragos *et al.* 1985; Smith *et al.* 1981).

Figure 6.1-5: Global distribution of the coral reef biome. (From: Wells and Hanna, 1992.)

Figure 6.1-6: The principal bioconstructional functional groups of the coral reef ecosystem. Reef construction is a result of the activities of stony coral-framework builders which are influenced by ‘modifier groups’ such as calcification enhancers, eroders and sediment operators. A key feature of the figure is the ‘potentiometer’ which shifts between framework-builders and non-framework-builders depending on changes in nutrients, grazing and physical conditions.

Ecosystem consequences of impacts. Coral reef ecosystems are characterized by slow removal and loss of nutrients and relatively low sediment accumulation (Johannes *et al.* 1983; Pomeroy *et al.* 1974). Human impact can switch the reef ecosystem to external cycling of nutrients and shift benthic dominance from corals to algae (D’Elia and Wiebe 1990).

6.1.10.5 Water circulation and quality

Human impacts on biodiversity. Coral reefs thrive in well circulated waters, both clear and naturally turbid (Done 1982). However, enhanced turbidity and freshwater

runoff from land is generally inimical to reef growth and development (Kühlmann 1988). Coral and sand mining and dredging can alter the configuration of reefs and hence water circulation patterns.

Ecosystem consequences of impacts. Coral atolls (necklaces of oceanic reefs and coral islands surrounding a central lagoon) provide good examples of functional differences driven by water circulation. Atolls may be characterized by their connection to surrounding water masses. The lagoons of ‘closed’ atolls are profoundly different from ‘open’ ones with increased nutrient retention time and productivity (Birkeland 1987).

6.1.10.6 Atmospheric properties

Human impacts on biodiversity. Increased seawater temperatures, possibly linked to global warming, and elevated UV-B radiation have been implicated in coral bleaching through the loss of symbiotic algae and/or their pigments (Williams and Bunkley-Williams 1991; Brown and Ogden 1992; Gleason and Wellington 1993). Bleaching stresses corals causing decreased calcification and reproductive capacity (Szmant and Gassman 1990), death and extirpation over wide areas (Glynn 1988). Increased seawater temperatures and rates of sea-level rise may ‘drown’ some reefs and cause a geographic shift in reef distribution (Buddemeier and Smith 1988). Some scenarios of global warming suggest an increased frequency of tropical storms, which may affect the rate of reef growth.

Ecosystem consequences of impacts. While reefs are sinks for CO₂ over geologic time, reef calcification causes pH reduction and release of CO₂ from seawater resulting in a net positive flux to the atmosphere (Smith and Buddemeier 1992). It is not expected that changes in reef biodiversity will have major impacts on the global atmosphere.

6.1.10.7 Landscape and seascape structure

Human impacts on biodiversity. Reefs protect the coast from the open ocean, fostering the development of a complex interdependent ‘seascape’ of ecosystems, including mangrove forests and seagrass beds. Human occupation and exploitation of the coastal zone cause profound changes in the configuration and interaction of the major ecosystems of the coastal seascape. Coastal clearing and deforestation for development, construction materials, charcoal and mariculture and destruction of seagrass beds, cause increased runoff of sediments and nutrients inimical to coral reefs. Reef biodiversity is dependent on the accessibility of adjacent ecosystems for feeding areas, nursery grounds, and flows of energy and materials (Ogden 1987, 1988; Figure 6.1-7).

Figure 6.1-7: The tropical coastal seascape showing buffering of the land from the ocean by reefs and the buffering of reefs from the land by coastal forests and seagrass beds (see text for detail). (After: Ogden 1987.)

Figure 6.1-8: The average coral density (cover) around Ishigaki Island, Ryukyus, Japan. The pollutant-absorbing effects of the shoreline forest belt is illustrated. (From: Kühlmann 1988.)

Ecosystem consequences of impacts. Coastal reefs attain their greatest development when isolated or otherwise protected from land run-off by coastal forests and adjoining seagrass beds which slow and baffle water movements allowing sediments to fall from suspension and nutrients to be absorbed. Kühlmann (1988) found that coral density was directly related to the preservation of this buffering capacity of forest margins in the Ryukyu Islands (Figure 6.1-8).

6.1.10.8 Biotic linkages and species interactions

Human impacts on biodiversity. Coral reefs are perhaps best known for the complexity of the biological relationships between species and functional groups. For example, Figure 6.1-9,a shows the hypothetical relationship between fishes, the ratio of corals/algae, and the major herbivorous sea urchin *Diadema* on undisturbed reefs in the Caribbean. The first critical disturbance was overfishing, which removed the larger size classes of predatory fishes as well as herbivorous groups. This impact ‘released’ *Diadema* populations from predation and competition and they attained artificially high population densities (Hay 1984; Figure 6.1-9,b). The mass mortality of *Diadema* in 1983–84 removed this remaining herbivore and the coral/algal ratio of Caribbean reefs shifted to an alternate state of algal dominance (Lessios *et al.* 1984; Carpenter 1986; Knowlton 1992; Hughes 1994; Figure 6.1-9,c).

This Caribbean basin-wide phenomenon has been exacerbated by circumstances that lower thresholds for macroalgal dominance over corals (Knowlton 1992): they include increased availability of nutrients (Hallock and Schlager 1986); increased sedimentation associated with deforestation (Cortes and Risk 1985); storm damage (Woodley *et al.* 1981), oil spills (Jackson *et al.* 1989), and mass bleaching of corals (Williams and Bunkley-Williams 1991). Similarly, ‘outbreaks’ of crown-of-thorns starfish populations in the Indo-Pacific can dominate the dynamics of many coral reefs (Done 1987, 1992).

Ecosystem consequences of impacts. The complex biotic linkages characteristic of reefs depend upon the ecosystem-

Figure 6.1-9: Model of the negative synergistic response of Caribbean coral reef communities to overfishing and sea urchin disease. Prior to overfishing, reefs existed in state (a), with high fish abundance, moderate urchin abundance, and large amounts of coral relative to algae. Overfishing (state b) led to a switch in the relative abundances of fishes and sea urchins, but no change in the relative abundances of coral and algae. Collapse of the sea urchins due to disease (state c) resulted in the replacement of corals by algae and further declines in fishes (From: Jackson, 1994b.)

wide effects of a few functional groups and organisms and influences such as nutrients which can shift the balance of reefs from framework-building corals to non-framework-builders such as benthic algae (Figure 6.1-6).

6.1.10.9 Microbial activities

Human impacts on biodiversity. Little is known about the human impact on reef microbial populations with the exception of inorganic nutrient processing. Under undisturbed conditions, virtually all microbial activity takes place within the benthos. Nitrogen gas is fixed by procaryotes on reef fronts and microbially transformed to nitrate, some of which is exported out of the reef system (Wiebe 1985). Phosphate is slowly exchanged by the benthos (Atkinson and Smith 1983).

Ecosystem consequences of impacts. Nutrient pollution (sewage, runoff) reduces N fixation and causes: (1) accumulation of PO₄ and fixed N within the sediments; (2) benthic macro-algal blooms; (3) micro-algal blooms in the water column. These blooms reduce light penetration which adversely affects the normal benthic plants and symbiotic algae. Prolonged exposure to high nutrients can lead to the smothering of corals and the transformation of the benthos into a low-diversity, benthic algal dominated system (D’Elia and Wiebe 1990).

6.1.10.10 Summary and relevance to human activities

Coral reefs, which are exploited by millions of people, are

acknowledged to be the most diverse marine ecosystem. Periodic disturbance plays a major role in the maintenance of their biodiversity, the persistence of which relies on the interconnections among often widely dispersed metapopulations, and on a low, steady supply of inorganic nutrients. The massive calcium carbonate structures of reefs are formed through the collaboration of unique functional groups including framework-builders (corals), facilitators (symbiotic algae) and grazers. Studies of reef communities through geological time or across gradients of diversity show that the composition of functional groups can vary greatly. However, changes in keystone species (single-species functional groups) can cause dramatic alterations in reef structure and functioning. The most common manifestation of disturbance is a shift from coral dominance to benthic algal dominance. Reefs protect the coast from the open ocean, fostering the development of a complex interdependent ‘seascape’ of ecosystems, including mangrove forests and seagrass beds. Reef biodiversity is dependent on adjacent ecosystems for feeding areas and nursery grounds and for protection against land runoff, allowing sediments to be trapped and nutrients to be sequestered. It is generally conceded that global reef diversity is declining from the impact of chronic human disturbances and is threatened by global climate change. Some effects of chronic human disturbance may be temporarily ‘invisible’: for example, few reef scientists worried about the effects of prolonged overfishing on corals until the demise of the sea urchin *Diadema* led to the wholesale replacement of corals by algae on these reefs (Figure 6.1-9). Similarly, some currently abundant species may already be doomed because of ‘extinction debts’ associated with habitat reduction. There appears to be little hope for the survival of reefs that are near relentlessly expanding coastal populations. Protection of more remote reefs will require inter-governmental co-operation in surveying, monitoring, comparative research and integrated coastal management within global sub-regions, such as the tropical western Atlantic, encompassing the geographic range of reef metapopulations and of key ocean processes.

6.1.10.11 Management implications

Reefs have responded to efforts to protect them from exploitation in parks and reserves (McClanahan 1994) and to pollution control (Maragos *et al.* 1985), and these efforts at the grassroots and local government level should be encouraged and expanded. However, the meta-population characteristics of most reef organisms argue strongly that the ultimate conservation of reefs, as much of the ocean environment, will be through inter-governmental management of human impact within ecologically defined sectors of the world’s tropical oceans.

6.1.11 Mangrove systems

6.1.11.1 Introduction

The major form of vegetation supporting biodiversity in tropical estuarine ecosystems is the intertidal forested wetland known as mangrove. About $240 \times 10^3 \text{ km}^2$ of mangroves (Lugo *et al.* 1990; Twilley *et al.* 1992) dominate tropical river deltas, lagoons and estuarine complexes developed from terrigenous sediments (Thom 1982). In addition, mangroves colonize shorelines and islands in sheltered shallow coastal waters formed principally from carbonate sediments. These are geomorphologically distinct regional landscapes with local variations in topography and hydrology that result in the evolution of distinct ecological types of mangroves (with respect to both structure and function) such as riverine, fringe, basin and dwarf forests (Lugo and Snedaker 1974). Although there are relatively few species of mangrove trees (54 species; Tomlinson 1986), mangrove ecosystems are nevertheless unique because they include structural niches and refugia for numerous non-mangrove species. Mangroves are salt-tolerant forested wetlands at the land–sea interface which form interdependent links between inland terrestrial landscapes and the nearshore marine environment (Macnae 1968; Chapman 1976; Odum *et al.* 1982; Tomlinson 1986; Gilmore and Snedaker 1993; Twilley *et al.* 1993). The dominant ecological ‘services’ of mangroves are the maintenance of nearshore marine habitats and the concomitant provision of food and refugia to a variety of organisms at different trophic levels (Odum and Heald 1972; Thayer *et al.* 1987; Sasekumar *et al.* 1992; Yañez-Arancibia *et al.* 1988, 1993; Rojas *et al.* 1992). Mangroves also play a major role in maintaining water quality and shoreline stability by controlling nutrient and sediment distributions in estuarine waters (Walsh 1967; Twilley 1988).

6.1.11.2 Human impacts on relevant biodiversity components

The coupling of mangroves to coastal waters is considered to be the most important link in the sustainability of

subsistence, commercial and recreational fisheries in estuaries and related nearshore marine habitats. Historically, the establishment of mangrove plantations promoted sustainable use of this valuable resource for forest products such as timber, fuelwood, tannins, pulpwood and charcoal in the Old World tropics (see Watson 1928; Saenger *et al.* 1983; Snedaker 1986). Recent forms of direct impact include the destruction of biodiversity by land uses such as aquaculture (shrimp ponds), agriculture (rice and salt ponds), urban development, and forest clear-felling for economic gain and other purposes (see Pannier 1979). Indirect loss of mangrove biodiversity components has resulted from human alterations of upland watersheds, causing diversion of freshwater flows (dams and canals), and deterioration of water quality from the input of toxic materials (heavy metals, oil spills, pesticides) and nutrients to rivers and coastal waters.

6.1.11.3 Productive capacity, biomass and decomposition

Ecosystem consequences of impacts: On a global scale, the highest species diversity and primary productivity occur in low-latitude regions where precipitation exceeds evaporation. Standing crop may reach 300–400 Mg/ha (Twilley *et al.* 1992; Saenger and Snedaker 1993). Human impacts change productivity, distribution and biomass accumulation by altering soil conditions such as salinity, sulphide concentrations, waterlogging, redox potentials, nutrient concentrations, soil structure and pH (Cintrón *et al.* 1978). Regional rates of litter production in mangroves are a function of water turnover and have been ranked according to ecological type as riverine > fringe > basin > dwarf (Pool *et al.* 1975; Twilley *et al.* 1986). The surficial hydrology is a critical factor in maintaining these diverse functions. Artificially reduced exposure to tides, and lower freshwater input, cause higher soil salinity (Cintrón *et al.* 1978), anoxia, and the accumulation of growth-inhibiting toxic substances such as hydrogen sulphide (Carlson *et al.* 1983; Nickerson and Thibodeau 1985; McKee *et al.* 1988) which result in increased stress (Hicks and Burns 1975). Regional-scale changes in freshwater surface inflow into mangrove areas have also caused reduction in the secondary productivity of tropical estuarine ecosystems due to the degradation of habitat and water quality of estuarine ecosystems. Changes in the species composition of mangrove communities alter the quality of leaf litter and result in different rates of decomposition and an altered quality of organic matter export (POC vs DOC) to the adjacent estuary (Boto and Bunt 1981; Twilley 1985, 1988; Snedaker 1989). Eliminating a given species of mangrove along zones of edaphic conditions may also alter specific types of refugia available to consumers (e.g. those offered by species with prop roots vs those with pneumatophores).

6.1.11.4 Soil structure and nutrients

Ecosystem consequences of impacts. Mangroves, particularly those in the genus *Rhizophora*, have a low decomposition rate of root biomass relative to root production, which results in the accumulation of organic matter in the soil and leads to the development of mangrove peat deposits (Snedaker 1993). Differences in litter quality among mangrove species also affect litter decomposition, leading to nutrient immobilization and accumulation (particularly nitrogen), and hence the fertility of mangrove soils (Twilley *et al.* 1986; Steyer 1988). Mineral accumulation is enhanced by mangrove prop roots and pneumatophores, which trap sediments suspended in the water column during low-velocity flooding. Coastal forested wetlands thereby enrich intertidal soils and retard the forces of erosion along the shoreline (Scoffin 1970; Lynch *et al.* 1989). In areas colonized by benthic calcareous algae (e.g. *Halimeda* and *Penicillus*), mangroves stabilize the new carbonate sediment and promote soil development. This process has led to a significant expansion of mangrove shorelines in southeast Florida along with a rise in sea level equivalent to about 23 cm per 100 years (Maul and Martin 1993; Snedaker *et al.* 1994). Mangrove rookeries are enriched in nitrogen and phosphorus which stimulate the productivity of mangrove vegetation. The density and diversity of herbivores is greater on mangrove island rookeries, compared to proximal islands that lack nutrient enrichment (Onuf *et al.* 1977). The so-called 'soil reclamation' projects in Africa, as well as in parts of Asia (cf. Ponnamperna 1984) for agriculture (and aquaculture) have reduced regional levels of coastal productivity due to loss of mangrove habitats. In many instances the conversion of organic-rich, pyritic mangrove soils leads to the formation of acid sulphate soils that are both extremely difficult to reclaim further, and incapable of supporting the original diversity of the landscape (cf. Dost 1973; Moorman and Pons 1975).

6.1.11.5 Water distribution, balance and quality

Ecosystem consequences of impacts. The conversion of coastal landscapes to agriculture has resulted in the deterioration of water quality in contiguous estuarine ecosystems. In Ecuador, pesticides from banana plantations have been implicated in the morphological deformity of shrimp in the Guayas River estuary (Taura syndrome). Water-borne heavy metals in the coastal regions of Brazil and Malaysia (Peterson *et al.* 1979) influence mangrove biodiversity and have impacts on the biodiversity and response of estuarine ecosystems. In Malaysia, the reduction of mangroves has resulted in increased turbidity of estuarine waters in the affected areas (Nixon *et al.* 1984). The nutrient removal capacity of the mangrove community *sensu lato* has been utilized for waste-water treatment in many tropical localities, particularly for nitrate

removal (Nedwell 1975; Clough *et al.* 1983). This practice is presumed to interfere with the dissolved organic matter (DOM) export from basin mangrove forests that augments aquatic primary production and the dynamics of phytoplankton (Prakash 1971; Prakash *et al.* 1973; Rivera *et al.* 1995).

6.1.11.6 Atmospheric properties

Ecosystem consequences of impacts. Nitrogenase activity has been observed on decomposing leaves, root surfaces (prop roots and pneumatophores), and in sediment. This enzyme makes an important contribution to the nitrogen budget in mangrove systems (Kimball and Teas 1975; Gotto and Taylor 1976; Zuberer and Silver 1978; Potts 1979; Gotto *et al.* 1981). Mangrove sediments in southern Florida fix nitrogen at rates of 0.4 to 3.2 g N/m²/yr (Kimball and Teas 1975; Zuberer and Silver 1978) and most of this fixation occurs in mangrove litter at specific stages of decomposition (Gotto *et al.* 1981; van der Valk and Attiwill 1984). This source of nitrogen can account for some of the nitrogen immobilization in leaf litter (Twilley 1988). Rates of nitrogen fixation in mangrove leaf litter are species-specific, depending on the chemical composition of the leaf. Thus, the contribution of this ecological process to the fertility of mangrove ecosystems may depend on the species composition and diversity of leaf litter, which differs among riverine, fringe, basin and dwarf zones. Mangrove forests also fix and store carbon in wood and organic-rich sediments. The total carbon sequestration in tropical coastal ecosystems is unknown, but it may contribute to the potentially significant carbon sinks in deltaic continental margins (Twilley *et al.* 1992).

6.1.11.7 Landscape and waterscape structure

Ecosystem consequences of impacts. River (and surface runoff) diversions that deprive tropical coastal deltas of fresh water and silt result in losses of mangrove species diversity and organic production, and alter the terrestrial and aquatic food webs that mangrove ecosystems support. Freshwater diversion of the Indus River to agriculture in Sind Province over the last several hundred years has reduced the once species-rich Indus River Delta to a sparse community dominated by *Avicennia marina*: it is also responsible for causing significant erosion of the seafront due to sediment starvation and the silting-in of the abandoned spill rivers (Snedaker 1984). A similar phenomenon has been observed in southwestern Bangladesh following natural changes in the distributary rivers of the Ganges, and the construction of the Farakka barrage which reduced the dry season flow of fresh water into the mangrove-dominated western Sundarbans. Freshwater starvation, both natural and human-induced, has had negative impacts on the rich vertebrate fauna (e.g. arboreal primates, deer, gaviel, large cats) of the Ganges

River Delta (Hendricks 1975; Das and Siddiqi 1985) and the Santa Marta lagoon (Ciénaga Grande) in Colombia (Botero 1990). Change in the species composition and distribution of mangroves and ecological types, such as fringe and basin forests, alters the quantity and quality of organic matter (DOM vs POC) contributed to adjacent estuaries (Twilley 1988). The effects of land-use changes at the landscape scale of tropical estuaries are also significant because of the dependence of marine organisms on estuarine conditions during the juvenile or adult stages of their life cycles (Yañez-Arancibia *et al.* 1994). The seasonal supply of organic matter by different primary producers, along with seasonal variations in physical constraints of organisms, such as temperature and salinity, provides a unique set of conditions for estuarine-dependent life cycles (Rojas *et al.* 1992). The fragmentation of mangrove-dominated landscapes may create the same types of problems for estuarine-dependent organisms that are associated with the fragmentation of upland forests, yet there has been little, if any, research on this topic.

6.1.11.8 Biotic linkages and species interactions

Ecosystem consequences of impacts. Organisms associated with mangrove forests may play many roles. In Malaysia, for example, bats that visit mangroves are also responsible for pollinating trees bearing the highly valued durian fruit. In Belize, wood-boring insects in mangroves are important to the formation of gaps and the specific architecture of mangrove trees (Feller 1993). Crabs are diverse in mangrove habitats (Jones 1984) with many functions such as contributing to plant zonation by differential seed predation (Smith 1987), to litter dynamics (leaf burrowing; Robertson 1986; Robertson and Daniel 1989; Twilley *et al.* 1993), and to nutrient dynamics (soil aeration from burrows; Smith *et al.* 1991) (see Box 6.1-2). Sponges, tunicates and a variety of other forms of epibionts on prop roots are equally diverse (Ruetzler and Feller 1988; Ellison and Farnsworth 1992) and may be sources of nutrition for higher level predators as well as influencing various processes in mangrove fringe forests. Finfish and macro-invertebrates may exert top-down control of community dynamics in fringe mangrove zones (Robertson and Duke 1990). Also, the diverse avifauna, mainly those that use mangroves for rookeries, control nutrient levels and foliage dynamics through nesting and the associated herbivory (cited above). These keystone guilds have disproportionate effects on the ecological processes of mangrove ecosystems, and illustrate the multiple roles of biodiversity in ecosystem functioning (Ray and McCormick 1992).

6.1.11.9 Microbial activities

Ecosystem consequences of impacts. The production and accumulation of mangrove peat occurs when root

Box 6.1-2: Crabs – a central ecosystem element in mangrove forests.

Crabs are extraordinarily abundant in many mangrove forests. They can make up nearly 80% of the macrofaunal biomass (Golley *et al.* 1962) and can reach densities of 80–90 per m² (Macintosh 1988). Two families of crabs are particularly associated with mangrove ecosystems (mangal) – the Grapsidae with 63 mangrove species, and the Ocypodidae with over 80 species (Jones 1984). These animals can have an enormous impact on ecosystem dynamics:

1. They can process as much as 70% of the leaf litter, and leaf processing by crabs in Australian mangrove systems can turn over litter at a rate in excess of 75 times that of microbial decay. The latter process predominates in New World mangrove ecosystems (Robertson and Daniel 1989).
2. Most of the mangal crabs feed on vascular plant material, including litter, but they also feed on green leaves, including seedlings. Seedling grazing, particularly by members of the genus *Sesarma*, may slow regeneration of these systems (Jones 1984) and crab seed predators greatly influence tree distribution in many mangrove forests. In the forests of Malaysia, Panama and Australia, grapsid crabs are the prime seed predators whereas in Florida snails occupy this functional role (Smith *et al.* 1989).
3. Mangal crabs not only fill every feeding niche but also occupy virtually all spatial dimensions of their habitat, showing species replacements horizontally from the sea inward and from the muddy substrate to the top of the canopy. Most, however, are burrowing forms (Jones 1984).
4. Crabs, through their burrowing activity modify the microtopography of the mangrove forest floor, not only influencing sediment texture distribution but also negatively affecting the abundance of surface algae (Warren and Underwood 1986).
5. Crabs of the mangrove forest positively influence tree productivity, and reproductive output, presumably by aerating the soil through burrowing activity and by decreasing sulphide levels. For this and many of the other activities described here Smith *et al.* (1991) have designated crabs as keystone species in mangrove systems.

production and mortality exceeds decomposition. The relative rate of below-ground production and decomposition in wetland plant communities depends on the presence of sulphate in seawater that is utilized by anaerobic sulphate reducers (Alongi 1988). In this regard, Snedaker (1993) has argued that in terms of climate change, changes in precipitation and freshwater run-off are the most important parameters (see also Pool *et al.* 1975) since each promotes mangrove [root] production and restricts root-peat decomposition by seawater-sulphate reducers. The succession of microbial processes also controls the transformation of nutritionally-poor mangrove leaf litter to a protein-rich food substrate which represents a significant contribution to the energy and nutrient budgets of tropical estuarine ecosystems (Heald 1971; Odum 1971; Fell and Master 1973).

6.1.11.10 Summary and relevance to human activities

A 1991 workshop on the status of mangroves of Southeast Asian coastlines (Sasekumar 1993) reported that the region has lost large areas of mangroves in the Philippines (80%), Thailand (50%), Indonesia (50%) and Malaysia (32%). This pattern is likely to continue as greater demands are placed on forest and fishery resources along with land use-changes along coastlines and in upland watersheds. The result will necessarily cause a change in the ecological characteristics of tropical estuaries. Many of the biodiversity components are sensitive to changes in physical conditions (salinity, turbidity), chemical balances (eutrophication) and biological changes (exotic species). The environmental quality of tropical estuaries relies on the unknown balance of the mosaic of ecosystem functioning, many components of which are still poorly understood. Major restoration projects in countries such as Colombia (Botero 1990), Pakistan (Qureshi 1990), Ecuador (Twilley *et al.* 1993) and Bangladesh (Siddiqi and Khan 1990) will challenge our ability to rebuild tropical estuaries and the dependent fisheries that have collapsed or been altered as a consequence of human interference.

6.1.12 Open oceans

6.1.12.1 Introduction

Open-ocean systems include all environments on Earth minus the landmasses and the continental shelf benthos. These systems comprise more than 70% of the Earth's surface, and over 90% of its habitable volume. Open-ocean ecosystems are unique in being almost completely devoid of higher plants, and depauperate in other forms of biogenic structure which is limited to drift-weed, terrigenous flotsam (especially wood) and the surfaces of other, usually motile living creatures. Primary production is dominated by phytoplankton, and averages one-fifth that of the mean terrestrial ecosystem (Valiela 1984), although turnover rates of oceanic plankton may be more than one order of magnitude greater than those of terrestrial vascular plants. Biomes within the open ocean are defined by the intersection of four factors: energy source for primary productivity, physical structure, depth/light attenuation, and latitude (Figure 6.1-10). Approximately 15% of described species are marine (Barnes 1989; May 1992). The diversity of open-ocean taxa is poorly known for both high and low taxonomic levels (Grassle and Maciolek 1992; Fuhrman and Davis 1994). The most conservative estimate for the total number of species in the open ocean – half a million – is still at least twice the number of species thus far described (May 1992), and estimates range up to 10 million (Grassle and Maciolek 1992; Poore *et al.* 1994; but see May 1992; Briggs 1994). Global phyletic diversity is dominated by oceanic taxa: 32 out of the 33 phyla are marine, and 15 of these phyla are marine endemics (Margulis and Schwartz 1988; Ray and Grassle 1991; Angel 1993). The variety of major functional groups in the marine environment also overshadows that found in other biomes. In particular, we must emphasize the significance of biodiversity within the microbial groups at the fundamental biochemical level. These are arguably the most unfamiliar, fundamentally 'different' life-forms in recent discovery (Fuhrman *et al.* 1992; Fuhrman and Davis 1994). And we have barely scratched the surface of the sediments (Grassle and Maciolek 1992; Poore and Wilson 1993; Poore *et al.* 1994). Species diversity is generally higher at low latitudes, with three peaks, dependent upon taxonomic group: photic zone, benthic environments at 2000 to 3000 m depth (mostly on the continental slope), and the abyssal plain (Vinogradova 1979b; Grassle 1991; Alongi 1992; Grassle and Maciolek 1992; Angel 1993; Poore and Wilson 1993; Brey *et al.* 1994). Life in the epipelagic zone is dominated by generalists with a dynamic metapopulation structure (Steele 1985, 1991). The deep benthos harbours a much higher diversity of species (Grassle and Maciolek 1992) and a higher proportion of local or regional endemics. Relationships among species in highly diverse deep-sea communities have not been well studied, and rates of dispersal of deep-sea species among

Figure 6.1-10: A heuristic view of the structure of open-ocean ecosystems.

geographic regions are also poorly known. There is an extremely important and dynamic link between the open ocean and coastal pelagic biomes due to the high prevalence of the larvae of many coastal marine organisms dependent upon pelagic dispersal.

6.1.12.2 Threats to the oceans

Increases in ultraviolet radiation may directly affect both phytoplankton and zooplankton in open ocean pelagic

areas. A steady increase in temperature amounting to 0.32 °C over the last 35 years has been observed at abyssal depths (Parrilla *et al.* 1994). Pollutants have been observed on the deep-sea floor in all areas where they have been looked for, and increases from atmospheric sources (LaFlemme and Hites 1978; Takada *et al.* 1994) are inevitable. The greatest flux of pollutants to the deep sea is likely to occur on continental margins where sediments from land sources accumulate. Human impacts on biodiversity in the open-

ocean biomes are summarized in Table 6.1-1. The biodiversity impact of changes in atmospheric gases (i.e. acid rain, global warming and ozone depletion processes) is uncertain, but likely to be significant. The reason for the uncertainty is partly that our knowledge of the biodiversity of the smallest epipelagic organisms is extremely poor. The likelihood of there being direct effects of these processes on the biodiversity of the megafauna is unknown. Fishery collapses in every sector of the world ocean point to a clear human impact on the diversity of top-level carnivores and herbivores in the epipelagic zone (Brown 1993; Norse 1993; Paine 1993; Anon. 1994), and major changes in community structure of oceanic ecosystems following the over-exploitation of dominant vertebrates and invertebrates have been observed in the Antarctic (Laws 1985), North Atlantic (Beddington and May 1982; Weber 1986), and Pacific Oceans (MacCall 1986; Cox 1993). Another human impact is the potential for acoustic noise to disrupt normal social and migratory behaviour of marine mammals and large teleosts.

There is insufficient baseline information about the distribution and abundance of deep-sea species to

determine whether or not major changes are occurring in deep-sea ecosystems (Grassle *et al.* 1990). The number of quantitative samples from the deep sea is minuscule, and increases in pollutants are not monitored in any area of the deep ocean. Furthermore, few scientists are capable of identifying species within even the better-known deep-sea taxa. Present information is insufficient for determining whether introductions or extinctions are taking place in either pelagic or benthic assemblages.

6.1.12.3 Productive capacity, biomass, decomposition and nutrient cycling

Human impacts on biodiversity. Most of the impacts mentioned above should be included here. There is evidence for major intra- and interspecific shifts in life history profiles of the dominant taxa in the open ocean due to over-extraction in fisheries and as by-catch (Nelson and Soule 1987; Rijnsdorp 1993; Stokes *et al.* 1993). Intraspecifically, there is evidence for response to overharvesting of sexually mature individuals, manifested as a reduction in age at first maturity and of maximum adult size. Fisheries have systematically reduced the

Table 6.1-1: Human impacts on the biodiversity of the open-ocean biomass.

1. References to the impacts are found in text.
2. Coastal systems extend to the limits of the continental shelf.
3. Epipelagic systems occur above 200 m; mesopelagic systems occur below 200 m.
4. Ranking of impact: ***expected serious impact; **expected moderate impact; *expected mild impact; indirect/direct effects may cascade impacts down down to other ocean systems.

abundance of all species of large organisms in the epipelagic zone.

Ecosystem consequences of impacts. Human impacts on productive capacity in the open ocean are predominantly nutrient-loading effects. However, alterations to biodiversity could have important secondary impacts on productive capacity or its spatial distribution. Shifts in the abundances of non-cetacean planktivores in Antarctic waters are probably a consequence of this impact (Valiela 1984). Elimination of large carnivores and herbivores should also have profound effects on the efficiency and form of open-ocean food webs. The effects of removal of large epipelagic species should cascade down to the rest of the water column, as these are significant agents of nutrient transport, both as living individuals undergoing frequent vertical migration, and as deadfall (Smith *et al.* 1989; Pfannkuche and Lochte 1993). Recent simulations of oceanic systems suggest that the effects of altering species composition are very difficult to predict, may be highly counterintuitive, and are dependent on relevant temporal and spatial scales (Yodzis 1988, 1994).

6.1.12.4 Sediment structure and nutrient pools

Human impacts on biodiversity. Removal of manganese nodules eliminates one important type of surface structure exploited by a distinct assemblage of epifauna (Thiel 1982). Reduction in epipelagic megafauna has compromised deadfall, which serves both as a source of nutrients and as a potential stepping-stone for dispersal of rift-associated organisms (Smith *et al.* 1989).

Ecosystem consequences of impacts. It is not known if human activity has yet had any significant impact on the biodiversity that affects sediment structure of infaunal dynamics in the deep sea. The possibility for impact exists through alteration of physical structure, chemical or radiological contamination, and alteration of nutrient inputs from surface waters. As for impact specifically emergent from loss of deep ocean soft sediment species, nothing can be surmised at this time. A cautionary note is in order, however. It is apparent that the diversity of microbial activity in the deep benthos is not only a key attribute of the system, but also of enormous potential value to humanity. The possibility of losing specific taxa or strains as a result of direct human alteration of sections of sea bottom should be taken seriously.

6.1.12.5 Water distribution, balance and quality

Human impacts on biodiversity. Principal concerns for the open ocean include toxic inputs (oil spills, ocean dumping of PCBs, heavy metals, pseudohormones, atmospheric inputs of toxic organic compounds), discharges, and alteration of nutrient regimes (Tanabe *et al.* 1984; Tanabe 1988; Cox, 1993). Although these are currently thought of as principally coastal phenomena

(GESAMP 1990), this is almost certainly a product of ignorance rather than an accurate reflection of fact. Even the most distant oceanic ecosystems have traces of human activities (Flegal *et al.* 1993).

Ecosystem consequences of impacts. The pervasive nature of chemical pollution suggests that open-ocean organisms and ecosystems are likely to experience levels of disruption at least as great as those observed in coastal systems. Existing data suggest, however, that substantially longer time scales are likely to be needed for recovery from such impacts. The biomagnification of toxins up through the food web could lead to significant changes in community structure if the larger apex organisms are negatively affected (Tanabe *et al.* 1984; Tanabe 1988; Addison 1989).

6.1.12.6 Feedbacks to atmospheric properties

Human impacts on biodiversity. Human impact on the biodiversity that influences atmospheric processes is difficult to ascertain because of our ignorance of which biogenic products are most important in regulating climate. Dimethyl sulphide, carbonyl sulphate and bromoform are gases that potentially can have an important impact on cloud formation or the greenhouse effect. All three gases are known to be produced by marine organisms (primarily the diatoms and non-calcifying coccolithophorids) (Charlson *et al.* 1987; Turner *et al.* 1988; Iverson *et al.* 1989; Kiene and Bates 1990). The relative abundance of these species and their distributions are poorly known, although anthropogenic activities (see Table 6.1-1 and above) will most likely alter their current status, because different taxa respond differently to eutrophication, chemical pollution, UV radiation and species introduction. Recent studies have suggested that oceanic phytoplankton may act as a carbon sink for globally increasing levels of carbon dioxide.

Ecosystem consequences of impacts. To the extent that the relative abundances of plankton producing carbonyl sulphate and dimethyl sulphide are impacted by human activities in the open ocean, change in at least the regional climate is likely to occur (Fuhrman and Capone 1991). This is a largely unexplored yet important field with possible wide-ranging ramifications given the potential ability of climate models to predict effects of global weather.

6.1.12.7 Landscape and waterscape structure

Human impacts on biodiversity. Patch dynamics are very important to the way open-ocean ecosystems function. Pelagic systems are heterogeneous at all scales (Steele 1985; Colebrook 1991; Kawasaki 1991): hydrodynamic structure predominates and is provided to oceanic systems principally by currents and waves from small-scale eddies, through warm-core rings of water moving across ocean basins, to trans-oceanic currents. Open-ocean biomes are not dominated by a biogenic physical structure, such as

angiosperms, that humans can alter. The extent of large floating mats of raftweed, such as *Sargassum*, may, however, have declined. Much of the benthic environment is very distant to most human activities, although mining and fish trawling in benthic habitats may differentially impact significant members of the benthic community (Watling and Langton 1994).

Ecosystem consequences of impacts. Physical structure is important to the functioning of the deep benthos, primarily because of the tunnelling activities and mixing of the sediments by specific biota, which alter biogeochemical cycling of nutrients and oxygen availability. Recent interest in mining and harvesting the deep sea will probably impact the structure of the seascape, although this effect has not been quantified.

6.1.12.8 Biotic linkages and species interactions

Human impacts on biodiversity. The decline of many marine fish stocks and the complete closure of many formerly productive marine fisheries signifies an important depletion in many top-level predators and herbivores in the open ocean. As one species becomes depleted, another is exploited until it, too, is scarce. Many of the formerly common fishes and marine mammals are now already rare, and two attributes of ocean systems may make them especially vulnerable. The first is pelagic recruitment. These species are subject to highly stochastic determinants and when disrupted sufficiently at large scales the outcome is highly unpredictable. Second, these systems are ordinarily very resilient so that a shift in the dominant species may be extremely difficult to reverse. This resilience is predicted from the prevalence of pelagic larval dispersal plus the likelihood that many adults can prey on the juveniles of many other species. Another important human impact comes from the introduction of marine species into novel environments via tanker ballast water, etc. (Carlton 1993; Carlton and Geller 1993; see 6.1.12.3). It is often assumed that open-ocean taxa are more cosmopolitan in distribution and that open-ocean systems should be less prone to the introduction of novel organisms, but this has yet to be tested.

Ecosystem consequences of impacts. Many of the organisms exploited by humans play pivotal roles in the food web, and because many of the top-level species are being exploited simultaneously, substantial changes in the composition of oceanic communities can be expected. The change in Antarctic communities due to whale harvesting, and the shift from a community dominated by bony fish to one dominated by cartilaginousfish in the Northwestern Atlantic are two examples of the transformation of open-ocean communities (Laws 1985; Weber 1986). Introduction of new organisms into an environment may result in the exposure of key organisms to novel diseases or predators (Carlton 1993; Carlton and Geller 1993), which can result

in dramatic shifts in community structure. These effects have been noticed most dramatically in coastal and coral reef systems. The lack of quantitative sampling over any time period in the open ocean precludes any firm conclusion on whether the effects of novel disease or predation are more or less important in oceanic systems. The recent mortalities of marine mammals along the Atlantic coastlines from viral epidemics (Visser *et al.* 1993) may reflect only the most visible outcome of some of the changes currently occurring in ocean ecosystems.

6.1.12.9 Microbial activities

Human impacts on biodiversity. The microbial world of both the pelagic and the benthic open ocean are poorly understood, in part because only now are molecular techniques revealing surprising information about the relatively high abundances of certain organisms (e.g. Archaea in surface waters) (Bergh *et al.* 1989; Giovannoni *et al.* 1990; Bolliger *et al.* 1991; Fuhrman *et al.* 1992, 1993). Its importance cannot be denied: the heterotrophic microbial loop accounts for over 70% of the total carbon and nitrogen in the euphotic zone (Fuhrman and Capone 1991). Chemical pollution could have a serious effect on microbial diversity by differentially impacting particular species.

Ecosystem consequences of impacts. Very little is known about the consequences of changing microbial communities because of the difficulty of identifying micro-organisms, and the dearth of knowledge about their ecology. Circumstantial evidence suggests that microbial processes such as degradation and the utilization of specific nutrients are most efficiently performed by specific microbes. Changes in the abundance of these organisms would thus alter the microbial loop. A high diversity of bacteria may be important in stabilizing microbial loops, given the large numbers of parasitic viruses found in open oceans (Bergh *et al.* 1989).

6.1.12.10 Summary and relevance to human activities

Although a great deal is known in principle about open-ocean biodiversity and potential human impacts, the empirical database is small, and our capacity to monitor and trace cause-effect relationships extremely limited. Many oceanic taxa are generalists, with a well-distributed population structure characterized by boom-and-bust cycles (Steele 1991). This may suggest that for many species, removal would have little overall effect on oceanic ecosystem processes; however, humans have simultaneously reduced the abundance of many organisms in higher trophic levels. This is predicted to cause a substantial change in the community structure and productivity of oceanic systems. Novel diseases and predators that will substantially change the functioning of certain oceanic ecosystems are likely to occur at some point

if the redistribution and introduction of organisms by humans continues. Changes in planktonic communities because of greenhouse effects, increased UV radiation, or food-web structural alterations may have large effects on our global climate because several of the climate-modulating gases are produced by relatively few plankton taxa. That we have overlooked open-ocean biodiversity in the past is understandable. That we should continue to do so is indefensible.

6.1.13 Lakes and rivers

6.1.13.1 Introduction

Freshwater ecosystems (lakes and rivers) cover about 2.5×10^6 km², less than 2% of the Earth's surface (Wetzel 1983). Only 0.014% of Earth's water occurs in the soils, rivers and lakes of the biosphere (la Riviere 1989): freshwater lakes contain 1.25×10^5 km³ of water (Wetzel 1983), while rivers contain about 1.2×10^3 km³ (Wetzel 1983). Combined, lakes and rivers contain about 0.009% of Earth's water (Wetzel 1983). Fresh water is a crucial resource for terrestrial ecosystems and human life. In addition, extensive riparian areas associated with rivers and lakes include some of the most productive ecosystems of the landscape. The small pool of water available for life is distributed irregularly, and water often limits terrestrial productivity and economic development (Gleick 1993). Climate and geomorphology determine the global distribution and diversity of fresh waters. Diversity of fresh waters across landscapes depends in part on regional geochemistry and land use. At the species level, diversity is best known for fishes (8400 species, 40% of the world's total fish diversity; WCMC 1992) and aquatic vascular plants (1022 species, Sculthorpe 1967). Other groups are less well known. For example, phytoplankton diversity may be in the order of 10^5 species, but only 10% or so of these are known (WCMC 1992).

Human impacts on biodiversity. A few common drivers account for virtually all human impacts on freshwater biodiversity components (Moyle and Leidy 1992; National Research Council 1992; Allan and Flecker 1993). The most important and widespread of these are:

1. Habitat loss and degradation, driven mainly by land transformations such as agriculture and forestry (Naiman *et al.* 1993) and by direct transformations of freshwater bodies by large water projects (Allan and Flecker 1993).
2. Species invasions and introductions (Lodge 1993).

3. Overharvesting (Moyle and Leidy 1992; Allan and Flecker 1993; Persson 1993).
4. Secondary effects, or cascading consequences of the loss of a native species, addition of an exotic, or overharvesting (Carpenter and Kitchell 1993).
5. Chemical pollution (National Research Council 1992).

Climate change is a potential driver with implications that are less certain than those of drivers 1–5 (Firth and Fisher 1991; Carpenter *et al.* 1992).

Methods for restoring damaged freshwater ecosystems are currently an area of active research (National Research Council 1992; Cooke *et al.* 1993). Rates of recovery are variable, and as a rule of thumb, are proportional to the water renewal time and the generation times of the longest-lived keystone organisms (see Box 5.2-1) (which are usually fishes or higher plants, including riparian trees). Water renewal times of the world's rivers are about 0.05 year and lake renewal times range up to 100 years (Wetzel 1983). Generation times of the keystone organisms are typically about a decade or longer.

Ecosystem consequences of impacts. Scientific certainty is relatively high for the following effects, except where noted otherwise.

6.1.13.2 Productivity, biomass, decomposition and nutrient cycling

Agriculture and construction activity promote erosion and nutrient loading which cause eutrophication of fresh waters. Input of sewage or household wastes can also result in eutrophication. Eutrophication involves increased primary production (especially of nuisance plants which reduce water quality; Cooke *et al.* 1993, increased storage of organic matter, and decreased decomposition due to anaerobiosis (National Research Council 1992). Dams can also increase primary production and storage of organic matter, while decreasing decomposition. In many cases exotic species, overharvesting, and their secondary effects have led to reduction of valuable fishery resources. Some kinds of chemical pollution can reduce fish stocks. Eutrophication is generally associated with increased nutrient availability and retention in freshwater ecosystems (Wetzel 1983). Exotic species and overharvesting have complex effects on sediments and nutrients. Exotic macrophytes alter sediment accumulation rates and biogeochemistry (Lodge *et al.* 1988), while changes in fish communities affect recycling rates of limiting nutrients (Lamarra 1975; Kitchell *et al.* 1979) and can shift the limiting nutrient between nitrogen and phosphorus (Elser *et al.* 1988; Carpenter and Kitchell 1993). Species composition, size distribution, and migratory behaviour of zooplankton and fishes largely determine the rates and spatial patterns of nutrient recycling in lakes (Carpenter *et al.* 1992; Schindler *et al.* 1993).

6.1.13.3 Water distribution, balance and quality

Eutrophication reduces water quality (Peierls *et al.* 1991, National Research Council 1992). Exotic species, overexploitation, and their secondary consequences, can either improve or degrade water quality. For example, exploitation of large fishes leads to increases in the numbers of small zooplanktivorous fishes, decreases in herbivorous zooplankton, excess algal growth and reduced water quality (Carpenter and Kitchell 1993). On the other hand, invasions of the zebra mussel in Eurasia and North America may improve water quality by filtering particles from the water. In rivers, the impacts of invasion or over-exploitation may depend very much on spatial scale and the elapsed time since last major flood (Grimm 1992). Chemical pollution reduces water quality.

6.1.13.4 Atmospheric properties

Anoxia, which has significant impacts on aquatic life, is a common consequence of eutrophication that is in a sense 'atmospheric'. Regional climates are affected by large freshwater bodies (Firth and Fisher 1991). Scientific certainty is relatively low for the following atmospheric effects.

Carbon dioxide: Most lakes have high $p\text{CO}_2$ relative to the atmosphere and therefore outgas CO_2 (Cole *et al.* 1994). However, the direction of gas exchange with the atmosphere can be reversed by adding nutrients or by adding fish that eat herbivorous zooplankton (Schindler 1977; Cole *et al.* unpublished). In either case productivity rises and uses the excess CO_2 , decreasing $p\text{CO}_2$ in the lake and causing CO_2 to invade from the atmosphere.

Methane: Anoxic sediments of wetlands, lakes and ponds produce considerable amounts of CH_4 at rates linked to landscape biodiversity and the biogeography of beaver (Carpenter *et al.* 1992). Beaver distributions control water retention, soil hydration and oxygenation, nutrient cycling and gas flux over vast continental areas (Naiman *et al.* 1993).

6.1.13.5 Landscape and waterscape structure

For ecosystem consequences of habitat loss and degradation, see 6.1.13.2 and 6.1.13.3.

Landscape and waterscape structures have been altered by river canalization, damming, reservoir construction, sedimentation and saltwater encroachment. Land-use practices that remove or alter riparian vegetation decrease the inputs of large woody debris to rivers and lakes, affecting cover, food resources and spawning habitat of fishes (Maser and Sedell 1994). Impacts of these structural changes are relatively well known scientifically.

6.1.13.6 Biotic linkages and species interactions

Because of the insularity of fresh waters, species introductions, overharvesting and management actions targeted on particular species can have effects that ramify throughout freshwater systems, affecting production, decomposition and nutrient recycling as well as other species (Power 1990; Carpenter *et al.* 1992; National Research Council 1992; Carpenter and Kitchell 1993; Lodge 1993; Persson 1993). These changes may also affect wildlife and waterfowl that use freshwater systems for drinking, habitat and food. Biodiversity of functional guilds in fresh waters can stabilize process rates in stressed ecosystems (Schindler 1990). This resistance to stress depends on the capacity of more tolerant species to replace the contributions of less tolerant ones (Frost *et al.* 1994). The resilience of freshwater ecosystems (i.e. their rate of recovery from perturbation) depends in part on biotic linkages and species interactions (Cottingham and Carpenter 1994). However, there is considerable scientific uncertainty about the responses of freshwater systems to changes in biodiversity. Species invasions have had a wide range of impacts on freshwater communities and ecosystems (Lodge 1993). For a given freshwater system, the nature and consequences of future invasions by exotic species may be difficult to predict.

6.1.13.7 Microbial activities

Eutrophication affects microbial activity, the biodiversity of microbial metabolic pathways, and the biodiversity of biogeochemical pathways through anaerobiosis (Wetzel 1983). Effects of species introductions and overharvesting on microbial activity are poorly resolved (Porter *et al.* 1988). Pelagic microbial activity closely tracks the productivity of phytoplankton, which can be effected by food-web structure (Pace 1993). Chemical pollution can directly and selectively affect crucial biogeochemical transformations (e.g. nitrification and sulphate reduction; Schindler 1990).

6.1.13.8 Summary and relevance to human activities

Landscapes and freshwater bodies are linked by powerful feedbacks. Terrestrial landscape diversity affects fresh waters by determining rates of erosion, siltation and nutrient input. Freshwater bodies are a magnet for human settlement and use, and human activities determine landscape biodiversity in the watersheds. Freshwater bodies are insular habitats in which biotic interactions can have major consequences. Species introductions and fish manipulations have significantly changed productivity, nutrient cycling and physical characteristics of fresh waters, and the net consequence of land-use changes and species introductions has been to increase the similarity among fresh-water ecosystems through eutrophication and community change.

Humans need fresh water for drinking, fishing, industry, irrigation, recreation and transportation (Schindler and Bayley 1990). These uses are impaired by landscape changes that fill, eutrophicate or pollute lakes and rivers, and by exotic species introductions and overharvesting that displace or eliminate living resources. A diversity of freshwater systems on the landscape is valuable as insurance against fluctuations in the productivity of, or need for, particular freshwater resources. Freshwater ecosystem diversity requires a diversity of riparian vegetation that buffers freshwater systems from upland erosion or other disturbances. Species management is a component of many methods for restoring fresh waters that have become degraded (National Research Council 1992). Species diversity guarantees a range of options for restorations that are potentially self-sustaining and consequently less costly. A major reason for sustaining freshwater biodiversity is to preserve options for maintaining high-quality water resources under different environments in the future.

6.2 Cross-biome comparisons

6.2.1 Productive capacity and biomass accumulation

6.2.1.1 Introduction

The response of ecosystem net primary production (plant growth) to biodiversity has two major components. One reflects the role of diversity in providing genotypes or species adapted to the full range of habitats within a biome, over the long term, including year-to-year climate variation and cycles of disturbance and recovery. The other concerns the response of production to diversity in a single year and at a single site. Because the relevant evidence, the underlying principles, and the feasible approaches for studying these two components are quite different, they are treated here in sequence.

Here, when referring to biodiversity, we generally refer to genetic and species diversity of the primary producers with the dominant life-form, i.e. trees in forests, grasses in grasslands, macro-algae in nearshore habitats and so on. Whole ecosystem biodiversity has additional dimensions, some of which may be critical determinants of production. For example, a relatively uncommon insect that preys on insect herbivores can have a major impact on production. At present, general tools for identifying species with a functional impact much larger than their biomass are not available (see Section 5.2.2). A focus on consequences of the diversity of primary producers in the dominant life form provides a starting point for understanding the functional role of biodiversity, but it clearly does not address the entire range of potentially important interactions.

6.2.1.2 Lessons from agriculture

Modern agriculture and plantation forestry are based on the premise that low-diversity ecosystems can be highly productive. While this premise is broadly validated in intensively managed ecosystems, the experience of agriculture highlights the critical sensitivity of low-diversity ecosystems to variation in climate and soils as well as outbreaks of pests and pathogens. Across all of the world's biomes, temporal and spatial variation in climate, soils, disturbance (e.g. fire, hurricanes) and biotic influences (e.g. pests, pathogens, dispersers, pollinators) are the rule rather than the exception. This variability,

much of which modern practices in agriculture and forestry are designed to suppress, establishes important constraints on the productivity of low-diversity natural ecosystems, especially over long time periods.

Lessons from agriculture provide useful guideposts for understanding the role of biodiversity in regulating production. First, when the genetic diversity of agricultural crops is severely limited, as when single hybrids are planted over large areas, pests and pathogens can be devastating. The outbreak of *Helminthosporium maydis* on CMS-T hybrid corn in 1969 and 1970 is an extreme example (Williams and Levings 1992). Second, maintaining productivity across a mixture of good and bad years is one of the most common motivations for multi-crop agriculture (Francis 1986; Vandermeer 1988; Swift and Anderson 1993). Third, progressive losses of productivity in some intensively farmed regions demonstrate that high productivity in low diversity ecosystems may be transient, depleting the accumulated capital of soil nutrients rather than operating on the sustainable supply.

6.2.1.3 Habitat variation in space and time

The role of biodiversity in modulating the sensitivity of production in natural ecosystems to variation in climate, soils and biotic factors is far from completely understood, but several lines of evidence establish its importance. Some of the evidence is very direct. For example, Tilman and Downing (1994) observed that biomass production was less drought-sensitive in high-diversity grassland plots than in low-diversity plots in the American Midwest (see Section 6.1.7.3). Year-to-year variations in climate can strongly favour different species in different years (Hobbs and Mooney 1991), a pattern that appears to result in higher productivity than occurs with continuous dominance by a single species.

Much of the evidence for the links between production and the biodiversity sufficient to provide species that thrive across a biome and over time is indirect and comes more from studies of pattern than of process. For example, vegetation differences between north- and south-facing slopes, drier upland and moister lowland sites, or sites on different soil types, are very common (Chabot and Mooney 1985). Whenever biodiversity falls below the minimum representing the suite of species or genotypes best adapted to each of the major habitat types within a biome, the overall vegetation becomes less well adapted to local conditions. With variation in slope, aspect, elevation, soils, moisture, temperature and wind, most biomes include several habitats that support distinctive local ecosystems. While these broad patterns do not necessarily maximize production in any particular year, they consistently yield solid compromises between short-term productivity and long-term persistence (Grime 1979; Chapin 1980). In

general, a single species does not thrive over the entire range of habitats in a biome. The uniform dominance of the tree *Metrosideros polymorpha* in natural Hawaiian habitats is an exception, though the recent history of biological invasions in Hawaii (Vitousek *et al.* 1987) points to the sensitivity of this pattern. Except in intensively managed systems, parallel changes in the habitat and in functional characteristics of the dominant plants make it likely that production increases with biodiversity, at least until each major habitat within a biome is occupied by least one species that thrives in it (Figure 6.2-1).

In many biomes, the vegetation on a patch depends on the time since disturbance, and the distinctions between early successional and late successional species are often striking (Tilman 1988). The failure of late successional species to thrive in early successional habitats and vice versa has been tested in many cases and supported experimentally in some, but not all, studies (e.g. Chapin *et al.* 1994). To the extent that the dominant species of one successional stage fail to thrive in others, production tends to increase with biodiversity whenever the increased biodiversity represents a specialist on an empty successional stage or time since disturbance (Figure 6.2-1).

Figure 6.2-1: A conceptual schematic of the response of average annual net primary production (NPP) to the biodiversity of plant species or genotypes in the dominant life-form, showing how mechanisms are likely to combine. The basic idea is that, at one site and in one year, low-diversity ecosystems subjected to intensive management can achieve nearly the same NPP as highly diverse ecosystems. In real biomes, however, spatial variation in climate and resources, temporal variation in climate, and successional dynamics related to disturbance history all increase the range of biodiversity over which NPP changes. NPP of any suite of species not skillfully chosen to provide plants adapted to the full range of habitats probably saturates even more slowly with biodiversity.

Vegetation production and persistence often reflect a balance between highly competitive species that use resources efficiently, and less competitive species that effectively colonize disturbed sites (Tilman 1993). A loss

of species anywhere along the continuum is likely to decrease long-term average productivity. Removal of strong competitors should result in less complete or efficient resource use, while a loss of good colonizers should lead to decreased production through incomplete establishment in recently disturbed areas (Tilman *et al.* 1994).

These three factors (spatial variability, temporal variability, and variation in time since disturbance) all tend to make average annual production an initially increasing function of biodiversity, without necessarily requiring more than one species of the dominant life form per habitat type. For a biome populated with a random selection of the possible species and genotypes, duplication of functional types or suites of adaptations would increase the number of species and genotypes at which long-term average production saturates (Figure 6.2-1).

Given these mechanisms that favour an increase in production with an increase in biodiversity, at what level of biodiversity should production reach a maximum, and how should this vary across biomes? In general, production should saturate at lower levels of biodiversity in biomes with lower levels of spatial and temporal complexity. Biomes certainly differ in the source and scale of the major modes of variation, but differences in the total amount or importance of variation are less clear. In tropical rain forests, the dominant sources of variation are probably related to small-scale gap dynamics (Martínez-Ramos *et al.* 1988) while in Arctic tundra, variation due to topography and soils is especially important (Chapin and Shaver 1989). In other biome types, year-to-year climate variation is a dominant source of variation. The response of grassland production to rainfall is a clear example of this (Sala *et al.* 1994). Precise quantitative estimates of the number of distinctive zones of habitat, climate and disturbance within each major biome are not yet possible. A rough but reasonable estimate is in the order of 10 substantially different zones per biome, with a range of perhaps 4 to 40. Additional experiments will be necessary before it is feasible to develop a more detailed accounting.

6.2.1.4 Production and resource augmentation

The mechanisms discussed above do not address the response to biodiversity of production at a single site in a single year. This topic is not well studied and neither the shape nor the quantitative limits of the response is generally known. In some cases, biological and biogeochemical characteristics related to production appear to saturate with a few species, even in a complex ecosystem like a tropical forest (Ewel *et al.* 1991). But when low-diversity ecosystems fail to develop complete canopies, as a consequence of the suite of plant species present or of interactions across trophic levels, increased diversity can lead to increased production (Naeem *et al.* 1994). Most of

the current hypotheses on the role of biodiversity in production at one site in one year are summarized by a resource augmentation model, which states that adding a species should increase production only if that species has access to, or prevents losses of, previously unused light, water or nutrients. Examples of mechanisms for increasing resource access or decreasing loss include symbiotic nitrogen fixation (for increased access to nutrients (Vitousek *et al.* 1987)), increased rooting depth (for increased access to water; Davis and Mooney 1986), improving the temporal match between nutrient release and uptake (Swift and Anderson 1993), releasing extracellular phosphatases into the soil solution (to increase phosphorus availability), faster canopy development (for increased light capture), increased leaf longevity (for decreased nutrient loss), and providing a refuge for ants or other defenders against herbivory (for decreased nutrient loss).

The resource augmentation model predicts that only a fraction of the many possible species additions should lead to increased production. But it also presents the possibility that many of the consequences of additions and deletions should be predictable on the basis of a species' pattern of resource utilization (Hobbie *et al.* 1993) or its relative abundance (Sala *et al.* 1996).

Anthropogenic impacts on the biosphere often result in changes in resource availability, in the efficiency with which resources are used for growth, or in the dynamics of resource turnover (Field *et al.* 1992). In some cases, these impacts may change the response of NPP to biodiversity. If for example, anthropogenic nutrient deposition changes the relative availability of limiting nutrients (Schulze 1989), or if a change in climate eliminates one or more species, potentially available resources may go unused without an increase in biodiversity. On the other hand, a change in resources or species composition could also make it possible for a smaller number of species to capture the available resources or to use the available resources more efficiently. It is also likely that the response of NPP to changes in biodiversity will differ with different anthropogenic impacts and that, for any particular anthropogenic impact, the NPP/biodiversity relationship will vary among biomes. Developing the understanding necessary to predict changes in the response of NPP to biodiversity in ecosystems impacted by altered climate, elevated CO₂, nutrient deposition, oxidants or species introductions should be a central objective of future studies. The role of biodiversity in regulating production at one site in one year involves different mechanisms from those governing the role of biodiversity across the whole array of habitats within a biome, and it is unlikely that relationships among species are the same in the two contexts. Thus, the response of production to biodiversity almost certainly saturates more slowly when both site-to-site and within-site mechanisms are operating. The quantitative response is not

yet known, but it is possible that species complementarity through resource augmentation could lead to increased production with two to several species or genotypes per site. A conservative minimum estimate is that accounting for resource augmentation for each site and year doubles the biodiversity necessary to saturate ecosystem production. Thus, the combination of the mechanisms related to resource augmentation and temporal and spatial diversity should lead to increasing production until the total reaches on the order of 20 species and/or genotypes in the dominant life-form of primary producers. The uncertainty of this estimate is very large. In addition, the persistence of these dominant life-form primary producers may depend on a number of other species, including pollinators, dispersers, nitrogen fixers, decomposers, herbivores and pathogens.

6.2.1.5 Biomass and disturbance

The role of biodiversity in regulating standing biomass is poorly studied. In most biomes, the major control on standing biomass is the frequency of disturbance, including fire, severe weather, and pest and pathogen attacks (e.g. Bonan and Shugart 1989). Disturbance frequency regulates not only the size of the dominant plants but also the species present and, in some cases, the presence or absence of a major growth form, e.g. trees (Hughes *et al.* 1991). Effects of single species on disturbance frequency have been documented (D’Antonio and Vitousek 1992), and resistance to pests and pathogens is one of the best-known benefits of multi-crop agriculture.

Increasing biodiversity could potentially decrease the frequency or intensity of many types of disturbance. Effects of biodiversity on disturbance by pests and pathogens are relatively well known, at least for agriculture. Biodiversity could decrease fire frequency, especially in ecosystems where single species enhance flammability (D’Antonio and Vitousek 1992). While increased biodiversity would not reduce the frequency or intensity of severe weather, it could reduce the intensity of disturbance through interspecific or population differences in tolerance to the extreme weather.

To the extent that increasing biodiversity decreases the frequency and intensity of disturbance, it should lead to increased standing biomass. It is not feasible, at this point, to even speculate on the number of species required to saturate the long-term average standing biomass.

6.2.2 The soil system

6.2.2.1 Introduction

The widespread effects of human activities on soils are of global concern because of increased emissions of 'greenhouse' gases, accelerated erosion and desertification, and declining fertility in soils supporting some of the highest population densities in developing countries (World Resources Institute 1992-3). Human-induced soil degradation by wind, water and pollution amounts to about 24% of the inhabited land area of the globe (Oldeman 1994). Changes in climate, atmospheric CO₂ concentrations and UV radiation are affecting soils and vegetation in regions of the world remote from direct effects of human activities (IPCC 1992). Disruption of soil processes from atmospheric pollution, changes in land use, management practices and intensive use of agrochemicals are also affecting freshwater and marine systems as a consequence of increased transfers of sediment, nutrients and toxins from land to water.

Losses of genetic and species diversity below ground resulting from human impacts on the biosphere are largely undocumented in comparison with estimates of extinction rates above ground. Biodiversity in soils, however, is not simply an attribute of the living biota. Unlike above-ground systems, the physical and biochemical properties of dead organic matter (litter and soil organic matter fractions) confer important functional attributes on soils which are integral to biogeochemical cycles. The structural and biochemical characteristics of soils vary both with depth in the profile and in relation to the parent materials, topographic variation, climate gradients and vegetation cover within and between systems. This spatial heterogeneity constitutes a mosaic of sinks and sources for surface water, sediment and trace gases which is important for stabilizing soil processes at aggregate, patch, plot, ecosystem and landscape scales.

The functional importance of biodiversity for the maintenance of soil fertility remains one of the most fundamental gaps in current understanding of terrestrial ecosystems (Swift and Anderson 1993; Anderson 1994). Indeed, the total diversity of the soil biota, as a starting point for this assessment, has not yet been determined for any natural system (Lee 1991). As a consequence of this dearth of comparable information on biodiversity in soils for the different biomes, this review has been developed in the style of a biome essay rather than a cross-biome synthesis as originally intended.

6.2.2.2 Lessons from agriculture

Human impacts on biodiversity. Most of the annual flux of carbon and nutrients in soils from tundra to tropical rain forest occurs in the top 5–10 cm of the profile despite the considerable variation in biomass and primary productivity above ground along this gradient. Structural characteristics of litter cover and the soil surface to a few millimeters depth partition the beneficial or destructive effects of rainfall (Papendick 1994). The animal and microbial communities occupying these critical soil interfaces are highly complex even in natural systems with low biodiversity of plant species. At the molecular and organism level, biodiversity in soils is very high. A single gram of temperate forest soil could contain 10⁹ individual cells comprising 4000–5000 bacterial types, of which less than 10% have been isolated and are known to science (Torsvik *et al.* 1990; Klug and Tiedje 1994). More than 500 species of soil invertebrates have been recorded from a beech (*Fagus sylvatica*) forest (Schaefer and Schauer mann 1990) and new records are still being added to a list of 2500 species of fungi from a nature reserve covering a few hectares in southwest England (Hawksworth 1992). Species richness declines towards the poles but assumptions regarding the simplicity of communities at high latitudes generally ignore the complexity of below-ground systems. Even simple moss tussock communities in the Antarctic Peninsula have complex food webs linking over a hundred species of algae, protozoa, nematodes, tardigrades, collembola and mites plus unknown numbers of fungal and bacteria species (Davis 1981).

Significant loss of biodiversity can occur when natural habitats are modified or converted to intensive permanent cultivation (Paoletti *et al.* 1992; Anderson and Swift 1993; Freckman and Ettema 1993; Lavelle *et al.* 1994). The larger, surface-living invertebrates disappear first with the destruction of litter habitats which provide food and living space. Dead tree boles and branches containing many wood-decomposing invertebrates and fungi can be eliminated under intensive extractive forest management or plantation forestry (Gilot *et al.* 1992). Conversion of tropical forest to tree plantations or smallholder farming

systems can also result in changes in termite communities with the loss of highly diverse humivorous groups and an increase in wood/litter feeders which include damaging pest species (Wood *et al.* 1977). In New Zealand, improvement of temperate pastures with legumes and exotic grasses eliminated indigenous earthworm species and enabled European lumbricids to become established (Lee 1985). In contrast, European lumbricids maintained marginal populations in US prairies in relation to native *Diplocardia* species because of their intolerance of high summer temperatures (James 1991). However, these exotic earthworms have invaded many mesic habitats where there is a low diversity of indigenous species (Hendrix *et al.* 1992).

Communities of smaller invertebrates live within the highly complex microscopic structure of litter and soil habitats. Anderson (1978) showed that the diversity of mite (Cryptostigmata) species was closely related to microhabitat diversity in organic soils developed under a single tree species. Changes in litter quality or the introduction of plant species with faster decay rates reduces habitat complexity. Improvement of pasture quality to support higher stock densities reduces the thatch of litter on the soil surface and thus the habitat space for the associated micro-arthropod communities (Hutchinson and King 1980), but earthworms living within the mineral soil respond positively to increased grass and dung quality (Knight *et al.* 1992; James 1992).

Mechanical cultivation is highly destructive to most invertebrate groups. The microbiota (nematodes, protozoa, micro-fungi and bacteria) are the main groups surviving in intensively tilled soils (Hendrix *et al.* 1986; Freckman and Ettema 1993). Agrochemicals also reduce the taxonomic and genetic diversity of soil micro-organisms (Domsch *et al.* 1983; Atlas *et al.* 1991). Even so, total biodiversity in agricultural soils is likely to be greater than the total above-ground diversity of plants and animals in the natural systems from which they were derived. The adoption of zero or minimum tillage practices allows the resurgence of biodiversity in agricultural soils provided that sources of colonists are present in habit refugia around the field margins (Hendrix *et al.* 1986).

Ecosystem consequences of human impacts. Most soil organisms are small (<2 mm diameter) and manifest their specific effects at spatial and temporal scales orders of magnitude below those where process measurements are made in most ecological studies (Anderson 1988). As a consequence there is a poor understanding of the links between their proximate roles in biological transformations and processes operating at larger scales and over longer time intervals.

The roles of the soil biota can be described in terms of allogenic and autogenic processes proposed by Jones and Lawton (1995). The allogenic processes, such as carbon

and nitrogen mineralization, are direct products of soil organism metabolism. These are modified by changes in the quality of the resources they are processing as a consequence of changes in plant species composition, CO₂ and N enrichment of plants, or pollution. Autogenic processes involve the modulating effects of organisms where the consequences of their activities, such as removing litter, creating soil macropores or the release of prey from predation, influence mass or energy transfers much larger than their allogenic effects (Anderson 1995).

Microcosm studies have shown that different species and combinations of invertebrates and microorganisms have specific effects on the rates and products of carbon and nutrient fluxes. The feeding activities of collembola, mites, nematodes and protozoa have also been shown to change the composition and activities of bacterial and fungal communities in ways analogous to the effects of herbivores in above-ground communities (reviews by Anderson 1988; Verhoef and Brussaard 1990). The specific nature of allogenic and autogenic effects could be taken to support the 'Rivet Hypothesis' that the removal of each species deletes unique properties from community functions (Ehrlich and Ehrlich 1981; see Section 5.1). However, at an ecosystem level, the attributes of complexity in food webs are not apparent and fumigation treatments, which eliminate much of the biotic diversity in soils, usually show transient effects on soil processes; at least in the short term (Rovira 1976; Ridge 1976; Ingham *et al.* 1986). These results suggests that there is a high level of functional overlap in soil biological processes, with many organisms producing similar metabolic end products able to compensate for changes in community structure. On the other hand, microbial processes such as nitrogen fixation, which are carried out by a group of bacteria with intrinsically low diversity in soils, are susceptible to heavy metal contamination of soils (Brookes and Verstraete 1989). McGrath *et al.* (1988) have shown that the activity of *Rhizobium* associations with white clover (*Trifolium repens*) was drastically reduced by heavy metal concentrations from sewage sludge which were within legislative limits set by the European Community.

The activities of soil fauna are evident at the ecosystem level where functional groups are dominated by one or two species creating persistent artifacts (aggregates, burrows, incorporation of organic matter into soil) which have cumulative effects on soil properties (Anderson 1995). The elimination of earthworms, or the introduction of exotic species with different attributes to the indigenous community, has been shown to alter soil structure, aeration, surface water infiltration, the distribution of organic matter, pesticides and heavy metals, and total crop production (Lee 1985; Lavelle 1988; Clements *et al.* 1991). In Peru, the conversion of forest to improved pasture eliminated most of the soil macrofauna and populations of an exotic tropical

earthworm species, *Pontoscolex corethrurus*, then developed a biomass of 4 t/ha and dominated soil processes (Lavelle and Pashanasi 1989). Termites in semi-arid systems have similar key effects on soil structure and hydrology which can shift from beneficial to deleterious as a consequence of changes in climate or management. In the overgrazed grasslands of Ethiopia, scavenging of the little remaining grass and litter cover by termites leaves soil bare and susceptible to erosion (Wood 1991). Similarly, the bare ground around termite mounds in grassland fallows of West Africa can initiate erosion and land degradation when they reach high densities (Janeau and Valentin 1987). Conversely, the elimination of a single termite species in the Chihuahuan desert altered the soil water balance and resulted in shrubs replacing grass cover in experimental plots over a period of eight years (Elkins *et al.* 1986).

6.2.2.3 Soil organic matter

Components of diversity. Soil organic matter (SOM) contains on average twice the amount of carbon found in vegetation above ground and is a resource of extraordinary physical and biochemical complexity (Theng *et al.* 1989; Anderson 1991). Dead organic matter is essential to the functioning of most natural and derived soils not only as a complex habitat and resource base for a diverse biota, but also because it maintains the physical and chemical integrity of the system. Litter resource types (fruits, leaves, twigs, branches, coarse and fine roots) from species with different chemical compositions and decomposition rates regulate the rates of carbon and nutrient mineralization (Swift and Anderson 1993). Litter cover also protects the soil from wind and rain erosion, and influences water and heat transfer to the underlying soil (Lal 1994). During the process of decomposition, soil organic matter (SOM) is formed which can be chemically or physically stabilized by soil minerals to form different fractions with turnover rates ranging from years to centuries. The whole range of SOM fractions, operationally defined as fast, slow and passive, confer particular attributes on soil such as aggregate stabilization, complexing free aluminium, regulating soil moisture, forming ion exchange complexes and constituting sinks/sources of plant nutrients (Duxbury *et al.* 1989). There are, however, very different time scales over which these effects are manifested. Changes in litter and fast SOM fractions have rapid effects on soil physical processes and nutrient cycling but the slow and passive fractions have turnover rates ranging from decades to millenia. Consequently, the restitution of soil profile characteristics under natural vegetation cover following catastrophic disturbance can effectively operate outside the human time frame.

Ecosystem consequences of human impacts. The effects of changing resource diversity on soil properties fits the asymptotic model of Vitousek and Hooper (1993; see

Figure 5.2-1A) relating species richness to ecosystem functioning. Adding (or removing) resources until all the key resource types are represented has larger effects on a given process than further additions of representatives of those groups. For example, erosion control depends on the amount of litter cover for soil protection rather than the diversity of plant species making up the litter (Mbakaya *et al.* 1988). Similarly, the amount of soil organic matter depends upon the quality and quantity of resource inputs and not on vegetation diversity. Hence SOM accumulation in forests is related to the inherent fertility of the parent soil and not to tree species diversity.

Where resource types are the product of a keystone species the effects of changing diversity can be profound. Davies (1981) has described two Antarctic moss communities: a tall turf community dominated by two moss species and a moss carpet dominated by three species. The decomposition-resistant (low quality) stems of one moss in the tall turf contributed to SOM accumulation to a depth of 2 m under this community against only 0.2 m SOM accumulated under the moss carpet with more rapidly decomposing (high quality) species. Analogous effects on soil carbon pools are associated with changes in landuse between high quality broad-leaf woodlands and low-quality conifer plantations; or the introduction new keystone species with contrasting litter quality into communities with low diversity (Anderson 1991). In Hawaii, organic soils have developed under stands of a single tree species, *Metrosideros polymorpha* which produces a low-quality litter in response to limited N availability. The invasion of the monospecific stands by an introduced nitrogen-fixing tree, *Myrica faya*, which produces a rapidly decomposing litter, has changed the nutrient and organic matter balances of the ecosystem (Vitousek *et al.* 1987). The consequences of these changes for the biodiversity of soil organisms are unknown but are likely to be profound. More gradual increases in litter quality and SOM turnover are occurring over much of Europe where anthropogenic sources of N are saturating forest ecosystems leading to increased nitrate leaching and nitrous oxide emissions (Aber *et al.* 1989; Rosen *et al.* 1992). Conversely, increased C/N ratios in litter as a consequence of CO₂ enrichment of N-limited systems may be increasing carbon storage in SOM on a global scale (Allen 1990; Bazzaz 1990).

6.2.2.4 Functional importance of spatial complexity

Spatial components of biodiversity. Soils under undisturbed vegetation cover have high resilience to natural perturbations, such as storm events, cataclysmic litter inputs and extreme seasonality, so that losses of suspended solids or solutes are usually small in relation to the pools and fluxes within the system boundaries. The mass balance of carbon and nutrients in the system is maintained by transfers between sinks and sources which operate at

different scales from microsites to landscapes (Anderson 1995). Reciprocal processes, which stabilize the overall dynamics of the system, are manifest in soil organism populations (natality/mortality; emigration/immigration), nutrient cycling (mobilization/immobilization), carbon fluxes (plant growth/decomposition), water balances (runoff/infiltration) and soil development (erosion/weathering). These sink/source interactions are considered in other essays in this volume and are only briefly reviewed here.

The balance between processes of nitrogen mineralization/immobilization, and nitrification/denitrification, are important in regulating nitrate leaching and nitrous oxide emissions from soils. These N transfers occur between adjacent bacteria, on gradients within soil aggregates (Groffman *et al.* 1987; Parkin 1987), at the level of resource patches integrated by fungal hyphae on the forest floor (Rayner and Boddy 1988), in forest gaps (Vitousek and Denslow 1986) and between hill-slope and riparian zones of catchments (Peterjohn and Correll 1984; Gregory *et al.* 1991). Sinks and sources for methane similarly exhibit scaling related to aerobic and anaerobic regimes in soils (Crutzen 1991) from microsites within aggregates (King and Adamsen 1992), and between surface and underlying soil horizons (Whalen and Reeburgh 1990) through the patch scales associated with plant communities (Whalen *et al.* 1990) up to the landscape scale (Moore *et al.* 1990).

Hydrological processes are also buffered by spatial heterogeneity of surface water sources and sinks. In rain forest, high intensity storm events, combined with funnelled stemflow as a result of branching patterns of canopy emergents, may create saturated areas around the trunk bases and overland flow downslope from these areas. Exposed roots and buttresses, however, can act as effective barriers to downslope soil wash (Spencer *et al.* 1990). Van Hooff (1982) showed that splash erosion and overland flow in a deciduous woodland was determined by the differential palatability to earthworms of litter from the two tree species. Consumption of the more palatable litter in patches of one tree species in spring caused splash erosion, while patches of the less palatable species, where litter cover remained intact, formed sinks for surface water and sediment so that there were no net losses of sediment across the forest boundary. Soil loss rates are generally low under forest cover but severe erosion can occur in extensive plantations of teak (*Tectona grandis*) where ground cover vegetation is suppressed and the rapidly decomposing leaves give no soil protection from the high kinetic energy of canopy throughfall (Bell 1973).

Spatial heterogeneity of soil properties reduces the amplitude of sediment, solute and trace gas losses from terrestrial systems. Extreme events which exceed sink strengths at local scales may be contained with the patch mosaic sinks at ecosystem or landscape scales. Human activities have major impacts on the heterogeneity of soils

which affect terrestrial, aquatic and atmospheric processes.

Ecosystem consequences of human impacts. Changes in landuse resulting from traditional agricultural practices can increase spatial heterogeneity of ecosystems within the landscape as a consequence of habitat fragmentation. Further intensification of landuse reduces the patch heterogeneity of sources and sinks for trace gases and solutes, and increases the periodicity and amplitude of biogeochemical fluxes within the landscape (Burke and Lauenroth; see 6.2.4). As larger areas of arable agriculture, plantation forestry and pastures come under the same soil management practices and cropping cycles, trace gas fluxes and nutrient leaching can be synchronized across whole landscapes with knock-on effects for atmospheric and aquatic systems on regional and even wider geographic scales.

Extensive development of intensive agricultural practices has increased soil erosion by wind and water in many regions of Europe and North America (Lal 1994; Papendick 1994). The removal of hedgerows and buffer strips, levelling of field systems and intensive tillage have reduced sinks for transported material. Soil channelling and compaction also result in surface runoff exceeding the infiltration capacity and particle retention by the microtopography of inter-rill areas (Boardman 1991). Similarly, Hutsch *et al.* (1993) have shown that sink strengths for methane in agricultural systems are related to the use of inorganic fertilizer (decreased sink) and organic manures (increased sink). Uniform agricultural practices using inorganic fertilizers can therefore reduce sinks for methane across agricultural landscapes (Mosier *et al.* 1991). Atmospheric N deposition also reduces the sink strength of forest soils (Steudtler *et al.* 1989).

6.2.2.5 Summary and relevance to human activities

Soils contain high biological, biochemical and physical complexity which can be defined across all scales from the microscopic to landscape level. The biotic diversity below ground may be orders of magnitude higher than that above ground but total microbial diversity has not been fully documented in any system. Human activities reduce the diversity of species, resources and spatial heterogeneity through changes in land-use and the effects of pollutants but the functional importance of these changes are largely unknown. Processes dominated by a few species representing functional groups are at risk from the direct and indirect effects of human activities. Source/sink dynamics within systems buffer mineral element, trace gas and sediment fluxes. These processes become synchronized with increasing intensity of landuse and reduction of spatial heterogeneity. As a consequence the amplitude and periodicity of biogeochemical fluxes can override sinks within landscapes and result in net transfers between the atmosphere and adjacent systems which would otherwise

be accommodated within system boundaries. It is concluded that there is a high degree of uncertainty over the consequences of reducing biodiversity below ground to undefined threshold levels in any terrestrial systems.
